We know we cannot alter the number of those separate points on the retina which determine the limit of our powers of vision in one direction, but we may be able to increase enormously the number of particles of silver in our photographic picture by processes that will give finer deposits, and so, in conjunction with more perfect and larger photographic lenses, we may reasonably look for a great improvement in our sense of vision—it may be even beyond that given by the telescope alone; although it always will be something in favour of the telescope that the magnification obtained in the eye is about fifteen times greater than that obtained by photography when the image on the retina is pitted against the photograph of the same size, unless we use a lens to magnify the photograph of the same focal length as the eye, in which case it is equal. But we *may* go much further in our magnification of the photographic image. In other ways there is great promise when we consider the difference in the action of the eye and the chemical action in the sensitive film under the action of light. As I pointed out in the discourse I gave about four years ago in this theatre, the eye cannot perceive objects that are not sufficiently illuminated, though this same amount of illumination will, by its cumulative effect, make a photographic picture, so that there are ways in which the photographic method of seeing celestial bodies can be possibly made superior to the direct method of looking with a telescope.

With some celestial objects this has been already done: stars too faint to be seen have been photographed, and nebulæ that cannot be seen have also been photographed; but much more than this is possible: we may be able to obtain photographs of the surface of the moon similar to those I have shown, but on a very much larger scale, and we may obtain pictures of the planets that will far surpass the pictures we would see by the telescope alone.

I have mentioned that the distance at which the normal eye can best see things is about nine inches, as that gives the greatest angular size to the object while retaining a sharp picture on the retina; but, as many of us know, eyes differ in this power: two of the common infirmities of the eyes are long- or short-sightedness, due to the pictures being formed behind the retina, in the first case, and in front of it in the other. Towards the end of the thirteenth century it was found that convex lenses would cure the first infirmity, and, soon afterwards, that concave lenses would cure the second, as can be easily seen from what I have said about the action of these lenses; so that during the fifteenth and sixteenth centuries the materials for the making of a telescope existed; in fact, in the sixteenth century, Porta invented the camera obscura, which is in one sense a telescope. It seems very strange that the properties of a convex and concave lens when properly arranged were not known much earlier than 1608. Most probably, if we may judge from the references made by some earlier writers, this knowledge existed, but was not properly appreciated by them. Undoubtedly, after the first telescopes were made in Holland in 1608, the value of this unique instrument was fully appreciated, and the news spread rapidly, for we find that in the next year "Galileo had been appointed lecturer at Padua for life, on account of a perspective like the one which was sent from Flanders to Cardinal Borghese." As far as can be ascertained, Galileo heard of the telescope as an instrument by which distant objects appeared nearer and larger, and that he, with this knowledge only, reinvented it. The Galilean telescope is practically, though not theoretically, the simplest form. It is made of a convex lens in combination with a concave lens to intercept the cone of rays before they come to a focus, and render them parallel so that they can be utilized by the eye. It presents objects as they appear, and the picture is freer from colour in this form than in the other, where a convex eye-glass is used. It is used as one form of opera-glass at the present time. Made of one piece of glass in the shape of a cone, the base of which is ground convex, and the apex slightly truncated and ground concave, it becomes a single-lens telescope that can be looked upon just as an enlargement of the outer lens of the eye.

Galileo was undoubtedly the first to make an astronomical discovery with the telescope: his name is, and always will be, associated with the telescope on this account alone.

Very soon after the introduction of the Galilean telescope, the difficulties that arise from the coloured image produced by a single lens turned attention to the possibility of making a telescope by using the reflecting surface of a concave mirror instead of a lens. Newton, who had imperfectly investigated the decomposition of light produced by its refraction through a prism, was of opinion that the reflecting principle gave the greatest possibilities of increase of power. He invented, and was the first to make, a reflecting telescope on the system that is in use to the present day; thus the two forms of telescope—the refracting and reflecting—came into use within about 60 years of each other. It will be perhaps most convenient in briefly running through the history of the telescope, that I should give what was done in each century.

Commencing, then, with the first application of the telescope to the investigation of the heavenly bodies by Galileo in 1609, we find that the largest telescope he could make gave only a magnifying power of about 30.

The first improvement made in the telescope, as left by Galileo, was due to a suggestion—by some attributed to Kepler, but certainly used by Gascoigne—to replace the concave eye-lens that Galileo used by a convex one. Simple as this change looks, it makes an important, indeed vital improvement. The telescope could now be used, by placing a system of lines or a scale in the common focus of the two lenses, to measure the size of the image produced by the large lens; the axis or line of collimation could be found, and so the telescope could be used on graduated instruments to measure the angular distance of various objects; in fact, we have now in every essential principle the true astronomical telescope. It is useless as an ordinary telescope, as it inverts the objects looked at, while the Galilean retains them in their natural position. The addition, however, of another lens or pair of lenses reinverts the image, and we then have the ordinary telescope. It was soon found that the single lens surrounds all bright objects with a fringe of colour, always of a width of about one-fiftieth of the diameter of the object-glass, as we must now call the large lens; and as this width of fringe was the same whatever the focal length of the object-glass, the advantage of increasing this focal length and so getting a larger image without increasing the size of the coloured fringe became apparent, and the telescope therefore was made longer and longer, till a length of over one hundred feet was reached; in fact, they were made so long that they could not be used. A picture of one of these is shown, from which it can be easily imagined the difficulties of using it must have been very great, yet some most important measurements have been made with these long telescopes. Beyond the suggestions of Gregory and Cassegrain for improvements in the reflecting telescope, little was done with this instrument.

During the eighteenth century immense advances were made in both kinds of telescopes. With the invention of the achromatic telescope by Hall and Dollond, the long-focussed telescopes disappeared.

Newton had turned to the reflecting telescopes believing from his investigations that the dispersion and refraction were constant for all substances; this was found not to be so, and hence a means was possible to render the coloured fringe that surrounds bright objects when a single lens is used less prominent, by using two kinds of glass for the lens, one giving more refraction with somewhat similar dispersion, so that while the dispersion of one lens is almost corrected or neutralized by the other, there is still a refraction that enables the combination to be used as a lens giving an image almost free from colour.

In 1733, Hall had made telescopes having double object-glasses on this plan, but never published the fact. Dollond, who had worked independently at the subject, came to the conclusion that the thing could be done, and succeeded in doing it; the invention of the achromatic telescope is with justice, therefore, connected with his name.

Although this invention was a most important one, full advantage could not be taken of it owing to the difficulty of getting disks of glass large enough to make into the compound object-glass, disks of about four inches being the largest diameter it was possible to obtain. With the reflecting telescope, unhampered as it always has been by all except mechanical difficulties, advance was possible, and astronomers turned to it as the only means of getting larger instruments. Many most excellent instruments were made on the Newtonian plan. The plan proposed by Gregory was largely used, as in this instrument objects are seen in their natural position, so that the telescope could be employed for ordinary purposes.

Many were also made on the plan proposed by Cassegrain. The diagrams on the wall enable you to at once see the essential points of these different forms of reflectors.

About 1776, Herschel commenced his astronomical work; beginning with reflecting telescopes of six or seven inches, he ultimately succeeded in making one of four feet aperture with these instruments. As everyone knows, most brilliant discoveries were effected, and the first real survey of the heavens made.

Herschel's larger telescopes were mounted by swinging them in a surrounding framed scaffolding that could itself be rotated. The smaller ones were mostly mounted on the plan of the one now before us, which the Council of the Royal Astronomical Society have kindly allowed me to bring here. The plan nearly always used by Sir William Herschel was the Newtonian, though for the larger instruments he used the plan proposed years before by Le Maire, but better known as the Herschelian, when the observer looks directly at the large mirror, which is slightly tilted, so that his body does not hinder the light reaching the telescope. In all cases the substance used for the mirrors was what is called speculum metal.

During the present century the aperture of the refracting telescope has increased enormously; the manufacture of the glass disks has been brought to a high state of perfection, particularly in France, where more attention is given to this manufacture than in any other country. Early in the century the great difficulty was in making the disks of flint glass. M. Guinand, a Swiss, beginning in 1784, succeeded in 1805 in getting disks of glass larger and finer than had been made before, and refractors grew larger and larger as the glass was made. In 1823 we have the Dorpat glass of 9·6 inches, the first large equatorial mounted with clock-work; in 1837 the 12-inch Munich glass; in 1839 the 15-inch at Harvard, and in 1847 another at Pulkowa; in 1863 Cooke finished the 25-inch refractor which Mr. Newall gave, shortly before his death last year, to the Cambridge University.

This telescope the University has accepted, and it is about to be removed to the Observatory at Cambridge, where it will be in charge of the Director, Dr. Adams. In accordance with the expressed wish of the late Mr. Newall, it will be devoted to a study of stellar and astronomical physics. There is every prospect that this will be properly done, as Mr. Frank Newall, one of the sons of the late Mr. Newall, has offered his personal services for five years in carrying on this work. Succeeding this we have the 26-inch telescope at Washington, the 26-inch at the University of Virginia, the 30-inch at Pulkowa, and the 36-inch lately erected at Mount Hamilton, California—all these latter by Alvan Clark and his sons. By Sir Howard Grubb we have many telescopes, including the 28-inch at Vienna. Most of these telescopes have been produced during the last twenty years, as well as quite a host of others of smaller sizes, including nearly a score of telescopes of about 13 inches diameter by various makers, to be employed in the construction of the photographic chart of the heavens, which it has been decided to do by international co-operation.

The first of these photographic instruments was made by the Brothers Henry, of the Paris Observatory, who have also made many very fine object-glasses and specula, and more important than all, have shown that plane mirrors of perfect flatness can be made of almost any size; the success of M. Lœwy's new telescope, the equatorial *coudé*, being entirely due to the marvellous perfection of the plane mirrors made by them.

The reflecting telescope has quite kept pace with its elder brother.

Lassell in 1820 began the grinding of mirrors, he like Sir William Herschel working through various sizes, finally completing one of 4 feet aperture, which was mounted equatorially. Lord Rosse also took up this work in 1840; he made two 3-foot specula, and in 1845 finished what yet remains the largest telescope, one of 6 feet aperture. All these were of speculum metal, and all on the Newtonian form. In 1870, Grubb completed for the Melbourne Observatory a telescope of 4 feet aperture, on the Cassegrain plan, the only large example. This is of speculum metal. In 1856 it was proposed by Steinheil, and in 1857 by Foucault, to use glass as the material for the concave mirror, covering the surface with a fine deposit of metallic silver in the manner that had then just been perfected. In 1858, Draper, in America, completed one on this plan of 15 inches aperture, soon after making another of 28 inches. In France several large ones have been made, including one of 4 feet at the Paris Observatory: in England this form of telescope is largely used, and mirrors up to 5 feet in diameter have been made and mounted equatorially.

Optically the astronomical telescope, particularly the refractor, has arrived at a splendid state of excellence; the purity of the glass disks and the perfection of the surfaces is proved at once by the performance of the various large telescopes. No limit has yet been set to the increase of size by the impossibility of getting disks of glass or working them, nor is it probable that the limit will be set by either of these considerations. We must rather look for our limiting conditions to the immense cost of mounting large glasses, and the absorption of the glass of which the lenses are made coming injuriously into play to reduce the light-gathering power, though it will be probably a long time before this latter evil will be much felt.

With the reflecting telescope the greater attention given to the working and testing of the optical surface has enabled the concave mirror to be made with a certainty that the earlier workers never dreamed of. The examination of the surface can be made optically at the centre of curvature of the mirror in the manner that was used by Hadley in the beginning of the last century, and revived some years ago by Foucault, who brought this method of testing specula to a high degree of perfection; in fact, with the addition of certain methods of measuring the longitudinal aberrations we have now a means of readily testing mirrors with a degree of accuracy that far exceeds the skill of the worker. It enables every change that is made in the surface during the progress of the figuring, as the parabolization of the surface is called, to be watched and recorded, and the exact departure of any part from the theoretical form measured and corrected; mirrors can be made of very much greater ratio of aperture to focal length. I have one here where the focal length is only 2¼ times the aperture: such a mirror in the days of speculum metal mirrors with the methods then in use would have necessarily had a focal length of about 20 feet. The difference in curvature between the centre and edge of this mirror is so great that it can be easily measured by an ordinary spherometer, amounting as it does with one of 6 inches diameter to 3/10,000 of an inch, an amount sufficient to make the focus of the outer portion about 1 inch longer than the inner when it is tested at the centre of curvature. The diagram on the wall, copied roughly from one of the records I keep of the progress of the work on a mirror during the figuring, shows how this system of measurements enables one to follow closely the whole operation.

The use of silver on glass as the reflecting surface is as important an improvement in the astronomical telescope as the invention of the achromatic telescope. It gives a permanency to a good figure once obtained that did not exist with the mirrors of speculum metal. To restore the surface of silver to the glass speculum is only a small matter now. How readily this is done may be seen by the practical illustration of the method I will give. I have here two liquids—one a solution of the oxide of silver, and another a reducing agent, the chief material in solution being sugar. I pour the two together in this vessel, the surface of which has been cleaned and kept wet by distilled water, which I shall partly empty, leaving the rest to mix with the two solutions; you will see in the course of about 5 minutes the silver begin to form, eventually covering the whole surface with a brilliant coating that can be polished on the outer surface as bright as that you will see through the glass.

Reflecting telescopes have advantages over the refracting

telescopes in many ways, but in some respects they are not so good. They give images that are absolutely achromatic, while the other form always has some uncorrected colour. They can be made shorter, and as the light-grasping power is not reduced by the absorption of the glass of which the lenses are made, it is in direct proportion to the surface or area of the mirror. They have not had in many cases the same care bestowed upon either their manufacture or upon their mounting as has been given in nearly every case to the refracting telescope. Speaking generally, the mounting of the reflecting telescope has nearly always been of a very imperfect kind—a matter of great consequence, for upon the mounting of the astronomical telescope so much depends. To direct the tube to any object is not difficult, but to keep it steadily moving so that the object remains on the field of view requires that the tube should be carried by an equatorial mounting of an efficient character. The first essential of such a mounting is an axis parallel to the axis of rotation of the earth. The tube, being supported on this, will follow any celestial object, such as a star, by simply turning the polar axis in a contrary motion to that of the earth at the same rate. If we make the telescope to swing in a plane parallel to the polar axis, we can then direct the telescope to any part of the sky, and we have the complete equatorial movement. There are several ways in which this is practically done: we can have a long open-work polar axis supported at top and bottom, and swing the telescope in this, or we can have short strong axes. As examples of the first, I will show you pictures of the mountings designed for Cambridge and Greenwich Observatories some forty years ago by Sir G. Airy, lately and for so long our eminent Astronomer-Royal; and as examples of the other form, amongst others, the large telescope lately erected at Nice, and also the larger one at Mount Hamilton, California, now under the direction of Prof. Holden.

The plan of bringing all the various handles and wheels that control the movement of the telescope and the various accessories down to the eye end, so as to be within reach of the observer, is carried to the highest possible degree of perfection here, as we can see by an inspection of the picture of the eye end of this telescope. The observer with the reflecting telescope is, with moderate-size instruments, never very far from the floor, but in the case of the Lick telescope he might have to ascend some thirty feet for objects low down in the sky; but, thanks to the ingenuity of Sir Howard Grubb, to whom the idea is due, the floor of the whole Observatory is made to rise and fall by hydraulic machinery at the will of the observer—a charming but expensive way of solving the difficulty, as far as safety goes, but not meeting the constant need of a change in position as the telescope swings round in keeping up with the motion of the object to which it is directed. The great length of the tube of large refractors is well seen in this picture of the Lick telescope; it suggests flexure as the change is made in the direction in which it points, and the consequent change of stress in the different parts of the tube.

The mounting of the reflector has been treated, if not so successfully, with more variety than in the case of the refractor as we shall see from the pictures I will show you, especially where the Newtonian form is used. The 4-foot reflector at Melbourne is mounted on the German plan, in a similar way to a refractor, and an almost identical plan has been followed by the makers of the 4-foot at the Paris Observatory. Lassell, who was the first to mount a large reflector equatorially, used a mounting that may be called the forked mounting, the polar axis being forked at its upper end, and the tube of the telescope swinging between the forks: a very excellent plan, dispensing with all counterpoising. Wishing to obtain certain conditions that I thought and think now favourable to the performance of the reflector, I devised a mounting where the whole tube was supported at one end on a bent arm; a 3-foot mirror was mounted on this plan in 1879, and worked admirably. The Newtonian form demands the presence of the observer near the high end of the telescope, and the trouble of getting him there and keeping him safely close to the eye-piece is very great. As we see from the various photographs, several means have been employed to do this, none of them quite satisfactory.

All the refracting telescopes of note in the world are covered by domes that effectually protect them from the weather; these domes are in some cases comparable in cost with the instruments they cover. It is not surprising, therefore, that efforts have been made to devise a means of getting rid of this costly dome and the long movable tube.

It was suggested many years ago that a combination of plane mirrors could be used to direct light from any object into a fixed telescope. This idea in a modified form has often been used for special work, one plane mirror being used as we see in the picture on the screen to throw a beam of light into a telescope fixed horizontally; for certain kinds of work this does admirably, but the range is restricted, as can be easily seen, and the object rotates in the field of view as the earth goes round. The next step would be to place the telescope pointing parallel to the axis of the earth and send the beam of light into it from the mirror, which could now be carried by the tube so that by simply rotating the tube on its own axis the object would be kept in the field of view. Sir Howard Grubb makes a small telescope on this plan, and some years ago proposed a somewhat similar plan. A sketch of this plan I will show you. You will see, however, that here again the range is restricted, and, to use the telescope, means would be required to constantly vary the inclination of the small mirror at one-half the rate of inclination of the short tube carrying the object-glass.

By the use of two plane mirrors, however, the solution of the problem of a fixed rotating telescope tube placed as a polar axis is solved. By having such a telescope with a plane mirror at an angle of 45° to the axis of the telescope in front of the object-glass, we can, by simply rotating the telescope, see every object lying on the equator; and by adding another similar plane mirror at an angle of 45° to the axis of the telescope, *as bent out at right angles by the first plane mirror*, and giving the mirror a rotation perpendicular to this axis, we obtain the same power of pointing the telescope as we have in the equatorial. The idea of doing this was published many years ago, but it was left to the skill and perseverance of M. Lœwy, of the Paris Observatory, to put it into practical use. He devised, and had made, a telescope on this principle, of 10½ inches aperture, which was completed in 1882. It has proved itself an unqualified success, and many other larger ones are now being made in Paris, including one of 23 inches aperture, now nearly completed, for the Paris Observatory.

A lantern copy of a drawing of this latter telescope will be thrown on the screen, in order that you may see what manifest advantages exist in this form of telescope. There is but one objection that can be urged—that is, the possible damage to the definition by the plane mirrors; but this seems, from what I have seen of the wonderful perfection of the plane mirrors made by the Brothers Henry, to be an unreasonable one—at any rate not an insurmountable one. In every other respect, except perhaps a slight loss of light, this form of telescope is so manifestly superior to the ordinary form that it must supersede it in time, not only for general work, but for such work as photography and spectroscopy.

ANNUAL VISITATION OF GREENWICH OBSERVATORY.

THE Report of the Astronomer-Royal to the Board of Visitors of the Royal Observatory, Greenwich, was read at the Annual Visitation on June 7. The Report presented refers to the year 1889 May 11 to 1890 May 10, and exhibits the state of the Observatory on the last-named day.

With respect to astronomical observations it is noted that, at the request of Dr. Gill, special attention has been paid to the oppositions of the minor planets Victoria and Sappho. Victoria has been observed 15 times on the meridian, and Sappho 9 times; while 244 observations have been made of 41 comparison stars for Victoria, and 151 observations of 42 stars for Sappho. At the request of Dr. Auwers, observations of the Sappho stars will be renewed in the autumn of this year, and an investigation made of the variation of personality with magnitude, for use in reducing the observations to a uniform system.

The Lassell, south-east, Sheepshanks, and Shuckburgh equatorials are in good working order. Great difficulty has been experienced at times in turning the south-east dome, and a careful examination shows that this may be largely due to the irregular shape of the cannon balls on which it rolls, and to a sagging of the dome curb in some parts.

The tube for the 28-inch refractor, which is of special construction, has been made by Sir H. Grubb in preparation for the object-glass which is now being figured. The experimental

4-inch object-glass referred to in the last Report was mounted on the Sheepshanks equatorial, and 18 photographs were taken with it last summer, the lenses being separated for photographic achromatism, and the crown lens reversed to correct for the spherical aberration introduced by the separation. The best distance of separation was determined, and the photographs obtained were found to be quite satisfactory. The completion of the 28-inch object-glass has been delayed presumably by the pressure of work on the 13-inch photographic telescopes, which have engaged so much of Sir H. Grubb's attention, but it is hoped that the new refractor will be ready for mounting very shortly.

The 13-inch photographic refractor, with 10-inch guiding telescope, by Sir H. Grubb, has been lately mounted in the new 18-foot dome, and one or two trial photographs have been taken with it.

Since the date of the last Report, 14 occultations of stars by the moon (9 disappearances and 5 reappearances) and 13 phenomena of Jupiter's satellites have been observed with the equatorials, or with the altazimuth. These observations are completely reduced to the end of 1889. The occultation of Jupiter by the moon on August 7 was observed with 5 instruments.

Comets have been observed with the Sheepshanks equatorial on 11 nights as follows: Comet *a* 1889 on 6 nights, Comet *d* 1889 on 1 night, Comet *a* 1890 on 4 nights.

The conjunction of Mars and Saturn on September 19 was observed with the south-east equatorial under favourable atmospheric conditions, and nineteen differential observations made of right ascension and north polar distance.

As regards spectroscopic and photographic observations, 457 measures have been made of the displacement of the F line in the spectra of 36 stars, and 20 of the *b* line in the spectra of 5 stars for determinations of motions of approach or recession. Observations of Algol on 7 nights confirm, as far as they go, the previous results indicating orbital motion. The observations of Spica made in past years are found by Prof. Bakhuyzen to be tolerably well represented on the hypothesis of orbital motion with a period of 4 days 0·386 hours, which agrees well with that recently discovered by Dr. Vogel with his photographic method. As the series of observations with the 12¾-inch refractor (extending over 15 years) will be shortly brought to a conclusion, it is proposed to discuss them with a view to the detection of orbital motion. The spectra of R Andromeda, χ Cygni, and Uranus, have been examined on several occasions, and Comet *e* 1889 on 1 night.

The sun has been free from spots on 211 days in the year 1889, the longest spotless period being October 23 to December 11. There were also eight other spotless periods of more than a fortnight. The mean daily spotted area in 1889 was 78, as compared with 89 for 1888: but the mean daily area for the latter half of the year was nearly twice as great as for the earlier half, being 103 as compared with 53. Again, the mean distance of spots from the equator was 5°·46 in the first six months, and 14°·72 for the last six; and both these facts thus point to the middle of the year 1889 as a well-defined date for the sun-spot minimum.

The following are the principal results for the magnetic elements for 1889:—

Mean declination	17° 34'·9
Mean horizontal force	3·9494 (in British units). 1·8210 (in metric units).
Mean dip	67° 22' 52" (by 9-inch needles). 67 23 58 (by 6-inch needles). 67 25 36 (by 3-inch needles).

In the year 1889 there were only two days of great magnetic disturbance, but there were also about twenty other days of lesser disturbance, for which tracings of the photographic curves will be published, as well as tracings of the registers on four typical quiet days.

The mean temperature of the year 1889 was 48°·8, being 0°·4 below the average of the preceding 48 years. The highest air temperature in the shade was 86°·6 on August 1, and the lowest 18°·7 on March 4. The mean monthly temperature in 1889 was below the average in all months excepting May, June, and November. In February and December it was below the average by 2°·4 and 2°·2 respectively, and in May above by [illegible].

The mean daily motion of the air in 1889 was 245 miles, being 39 miles below the average of the preceding 22 years. The greatest daily motion was 736 miles on October 7, and the least 25 miles on September 3. The greatest pressure registered was 15 lbs. on the square foot on October 7.

The number of hours of bright sunshine recorded during 1889 by the Campbell-Stokes sunshine instrument was 1156, which is about 146 hours below the average of the preceding 12 years, after making allowance for difference of the indications with the Campbell and Campbell-Stokes instruments respectively. The aggregate number of hours during which the sun was above the horizon was 4454, so that the mean proportion of sunshine for the year was 0·260, constant sunshine being represented by 1.

The rainfall in 1889 was 23·3 inches, being 1·3 inches below the average of the preceding 48 years.

It was mentioned in the last Report that the Indian invariable pendulums had been mounted in the Record Room under General Walker's supervision. The three pendulums have each been swung 8 times, at pressures of both 2 inches and 27 inches, and the observations completely reduced, giving the following results for number of vibrations in a mean solar day, reduced to vacuum, a temperature of 62°, an infinitely small arc, and sea-level; the corresponding values obtained at Kew being appended for comparison:—

Pendulum.		Greenwich.		Kew.
4	...	86,165·54	...	86,166·50
6	...	86,065·70	...	86,066·61
11	...	86,117·04	...	86,117·03

The tabulation of results for the period of the fifty years of observations will be completed at the end of this year, and will be useful for many purposes. In the twenty years' meteorological reductions, the values were grouped generally in months, mainly for the determination of diurnal inequalities of the thermometer and barometer. In the tables of meteorological averages now proposed, however, the values will be grouped by days, so as to exhibit mean values for each day of mean daily temperature, maximum, minimum, barometer, velocity of wind, frequency of gales, rainfall, and cloud, obtained from the Greenwich observations of fifty years, 1841–90.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator (Dr. Sandys, tutor of St. John's College) in presenting Sir Andrew Clark, Mr. Jonathan Hutchinson, Dr. John Evans, Prof. Sylvester, and Mr. A. J. Ellis for honorary degrees on June 10:—

Salutamus deinceps salutis ministrum, Aesculapii e filiis unum, quem idcirco praesertim Machaona nominaverim quod saeculi nostri oratorum cum Nestore ipso totiens consociatus est;—nisi forte, Romano potius exemplo delectatus, mavult Asclepiadis illius disertissimi nomen mutuari, quo medico et amico utebatur Lucius Licinius Crassus, saeculi sui oratorum eloquentissimus. In re publica partium liberalium studiosus, in re privata liberalitate singulari insignis, non modo medicinae sed etiam philosophiae et religionis penetralia ingressus est. Etiam antiquos meministis quondam non de corporis tantum salute sed etiam de rebus fere omnibus quae vitam anxiam et sollicitam reddant, ab ipso Aesculapio solitos esse oracula exposcere. Viri talis igitur, velut iurisconsulti Romani, domus, est velut civitatis oraculum, unde cives eius, ut Apollo Pythius apud Ennium dicit, consilium expetunt, non salutis tantum sed etiam "summarum rerum incerti," quos incepti certos "compotesque consili dimittit." Ergo virum, quem aut litterarum aut scientiae aut medicinae doctorem nominare potuissemus, iuris doctorem non immerito creamus.

Duco ad vos medicinae professorem emeritum, Regii Medicorum Collegii Londinensis praesidem, baronettum insignem, suavem, eruditum, eloquentem, ANDREAM CLARK

Etiam alter Aesculapii filiorum, Podalirius (nisi fallor), hodie nobis sese praesentem obtulit, quem a fratre suo idcirco disiungere neque possumus neque volumus, primum quod professoris in munere quondam erat collega eius coniunctissimus, deinde quod forte quadam domum vicinam atque adeo proximam incolit, denique quod dignitate non minore Collegio alteri praesidet, ubi

Britanniae chirurgi per tot annos quasi penates suos posuerunt. Medicinae studiosis nota sunt scripta eius per seriem longam edita, in quibus pars ea medicinae quae manu curat illustratur, et litterarum monumentis mandatur. Neque silentio praeterire possumus quaecumque de pathologia praesertim, quam quondam profitebatur, accuratissime scripsit; scilicet mortem ipsam, quae aliis tacet, huic velut rerum naturae vati et interpreti constat esse eloquentem. Neque prorsus intacta relinquimus quicquid de morborum contagione disputavit. Medicorum nemo fortasse Horatii verba in re medica saltem eruditius illustravit:—

delicta maiorum immeritus lues.

Duco ad vos Regii Chirurgorum Collegii praesidem, chirurgum illustrem, JONATHAN HUTCHINSON.

Archaeologiae studia nonnulli certe arida mentis nutrimenta arbitrantur. Hic autem etiam difficili in materia ingenii sui non minus facilis quam felicis alimentum invenit, qui etiam silices duros diu habuit in deliciis, ex ipsoque saxo doctrinae scintillam saepenumero excudit,

suscepitque ignem foliis atque arida circum
nutrimenta dedit, rapuitque in fomite flammam.

Quicquid lapidis, quicquid aeris, quicquid auri et argenti Britannia antiqua usurpabat, assidue conquisivit; conquisitum erudite illustravit. Britanniae nummorum investigator acerrimus, propterea etiam ultra fretum Britannicum numismate aureo honoris causa donatus est. Neque antiquis tantum thesauris operam dedisse videtur, sed etiam Societatis Regiae praefectus aerario, tot scientiis auxilium quotannis certatim flagitantibus, pecuniae publicae dispensator providus, aequus, benignus exstitit. Quondam Geologicae, iamdudum Numismaticae Societati praepositus, nunc etiam Antiquitatis peritorum Societati maximae summa cum dignitate praesidet. Quot scientiarum trans provincias aquilas suas felices tulit! Quid si non (velut alter ille quem hodie expectabamus)—quid, inquam, si non "nomen ab Africa lucratus rediit," tamen laudes eius Musae nullae "clarius indicant, quam Calabrae Pierides, neque

si chartae taceant quod bene feceris
mercedem tuleris.

Audite igitur ipsum Ennium viri huiusce praeconia praesagientem:

doctus, fidelis,
suavis homo, facundus, suo contentus, beatus,
scitus, secunda loquens in tempore . . .
multa tenens antiqua.

Duco ad vos virum de antiquitatis studiis praeclare meritum, JOANNEM EVANS.

Plusquam tres et quinquaginta anni sunt elapsi, ex quo Academiae nostrae inter silvas adulescens quidam errabat, populi sacri antiquissima stirpe oriundus, cuius maiores ultimi primum Chaldaeorum in campis, deinde Palestinae in collibus, caeli nocturni stellas innumerabiles, prolis futurae velut imaginem referentes, non sine reverentia quadam suspiciebant. Ipse numerorum peritia praeclarus, primum inter Londinenses Academiae nostrae studia praecipua ingenii sui lumine illustrabat. Postea trans aequor Atlanticum plusquam semel honorifice vocatus, fratribus nostris transmarinis doctrinae mathematicae facem praeferebat. Nuper professoris insignis in locum electus, et Britanniae non sine laude redditus, in Academia Oxoniensi scientiae flammam indies clariorem excitat. Ubicunque incedit, exemplo suo nova studia semper accendit. Sive numerorum θεωρίαν explicat, sive Geometriae recentioris terminos extendit, sive regni sui velut in puro caelo regiones prius inexploratas pererrat, scientiae suae inter principes ubique conspicitur. Nonnulla quae Newtonus noster, quae Fresnelius, Iacobius, Sturmius, alii, imperfecta reliquerunt, Sylvester noster aut elegantius explicavit, aut argumentis veris comprobavit. Quam parvis ab initiis argumenta quam magna evolvit; quotiens res prius abditas exprimere conatus, sermonem nostrum ditavit, et nova rerum nomina audacter protulit! Arte quali numerorum leges non modo poetis antiquis interpretandis sed etiam carminibus novis pangendis accommodat! Neque surdis canit, sed "respondent omnia silvae," si quando, inter rerum graviorum curas, aevi prioris pastores aemulatus,

Silvestrem tenui musam meditatur avena.

Duco ad vos Collegii Divi Ioannis Socium, trium simul Academiarum Senatorem, quattuor deinceps Academiarum Professorem, IACOBUM IOSEPHUM SYLVESTER.

Claudit seriem viri eiusdem aequalis, qui doctrinae rudimentis primum Salopiae, deinde Etonae, denique Trinitatis in Collegio maximo imbutus, eadem in Academia isdem e studiis lauream suam primam reportavit. Sed ne his quidem finibus contentus, etiam musices mysteria perscrutatus est, et philologiae provinciam satis amplam sibi vindicavit. Quanta perseverantia etiam contra consuetudinem, ut Quintiliani verbis utar, "sic scribendum quidque iudicat, quomodo sonat"! Quanta subtilitate de linguae Graecae et Latinae vocalibus disputat; quam minuta curiositate etiam patrii sermonis sonum unumquemque explorat! A poetis nostris antiquioribus exorsus, non modo saeculorum priorum voces temporis lapsu obscuratas oculis et auribus nostris denuo reddidit, sed etiam nostro a saeculo in dialectis variis usurpatam litterarum appellationem, signis accuratis notatam, posteritati serae cognoscendam tradidit. Venient anni (licet confidenter vaticinari) quibus dialectorum nostrarum tot varietates, non minus quam Arcadum et Cypriorum linguae antiquae, hominum e cognitione prorsus obsolescent; tum profecto viri huiusce scriptis cura infinita elaboratis indies auctus accedet honos.

Mortalia facta peribunt,
nedum sermonum stet honos et gratia vivax.

Interim a nobis certe sermonis Britannici conservator animi grati testimonium, honoremque diu debitum, diu duraturum accipiet.

Duco ad vos philologum insignem, ALEXANDRUM JOANNEM ELLIS.

At the annual election at St. John's College, on June 16, the following awards in Mathematics and Natural Science were made:—

Mathematics—Foundation Scholarships continued or increased: Bennett (£100), Reeves (£80), Alexander (£70), Dobbs (£60), Finn (£50), Gedge (£40), Hough (£80), Chevalier (£60), Pocklington (£80), Rosenberg (£50). Foundation Scholarships awarded: Wills (£60), Owen (£50), Schmitz (£40), Pickford (£40), Maw (£40). Exhibitions: Dobbs, Wills, Finn, Owen, Schmitz, Pickford, Maw, Robertson, Bloomfield, Spaight, Ayers, Morton. Proper Sizarship: Le Sueur. Natural Science—Foundation Scholarships continued or increased: Groom (£60), Hankin (£40), Horton-Smith (£40), Hewitt (£80), Lehfeldt (£80), Woods (£40). Foundation Scholarships awarded: Blackman (£40), MacBride (£60), Cuff (£40), Whipple (£40). Exhibitions: Woods, Baker. Proper Sizarship: Baker. Hutchinson Studentship for Pathological Research, Hankin. Wright's Prizes: Mathematics, Hough; Natural Science, Hewitt, Lehfeldt, MacBride. Hughes Prize for most distinguished student of the third year, Bennett (Mathematics). Hockin Prize for Experimental Physics, Lehfeldt.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 12.—"A Record of the Results obtained by Electrical Excitation of the so-called Motor Cortex and Internal Capsule in an Orang Outang (*Simia satyrus*)." By Charles E. Beevor, M.D., F.R.C.P., and Victor Horsley, B.S., F.R.S. (From the Laboratory of the Brown Institution.)

Having been engaged for some time in investigating the representation of motor function in the cortex of the bonnet monkey, we thought it advisable to perform the same in an anthropoid as likely thereby to gain a closer insight into the modes of representation in man.

We first describe the peculiarities noticeable in the configuration of the convolutions in the orang.

As in the bonnet monkey, after narcotization with ether, we divided the cortex into squares of 2 millimetres side, and excited the same with minimal stimuli from the secondary coil of an inductorium; a remarkably high intensity of the stimulus being required.

General Results.—The mode of representation of motor function was found to be highly specialized. The general plan was identical with that seen in the bonnet monkey in that the representation of each segment and part of the body in the orang was arranged in the same order as that according to which we found the representation of the primary movements to be grouped in the macacque monkey.

In addition to this, the areas for the representation of the different parts of the body we found not to be continuous with each other, but that between the areas of representation (for instance, of the face and the upper limb) there were regions of inexcitable cortex showing a degree of differentiation not obtained in the lower monkey.

A further remarkable evidence of specialization was noticeable in the fact that excitation of any one point elicited rarely more than one movement, and only of one segment, *e.g.* simple flexion of the elbow. Consequently, any sequence of movement or march was conspicuously infrequent.

Finally, the character of each movement and its localization was recorded.

After the cortex had been removed, we proceeded to stimulate the fibres of the internal capsule, and the results obtained confirmed those obtained from the bonnet monkey, and at the same time showed the relative position of the cortical areas.

The internal capsule was exposed by removing half of one hemisphere by a horizontal section; the outlines of the basal ganglia were then transferred to paper ruled with squares of 1 millimetre, and the resulting movement obtained by stimulating each of these squares contained in the internal capsule was recorded. The movements obtained correspond generally with the results which we have in another paper presented to the Royal Society, and read on December 12, 1889.

Physical Society, May 16.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Lord Rayleigh exhibited and described an arrangement of Huyghens's gearing in illustration of electric induction. This gearing consists of two loose pulleys mounted on the same axle, with an endless cord laid over them, the loops or bights of which carry weighted pulleys whose planes are parallel to the axis on which the upper pulleys turn. If one of the latter pulleys be started to rotate, the other one turns in the opposite direction until such time as the speed of the first one becomes constant. Whilst this constant speed is maintained, the second pulley remains stationary, one weight being raised and the other lowered, but on retarding the motion of the first pulley, the second begins to turn in the same direction as the first. It will be noticed that the phenomena are analogous to those which occur in electric induction, where starting or increasing a current in one circuit induces an opposite current in a neighbouring circuit, whilst decreasing or stopping a current induces one in its own direction. Lord Rayleigh pointed out that in this apparatus there is nothing strictly analogous to electric resistance, for the friction does not follow the same law. The analogy, he said, was complete as regards there being no change of potential energy, and the mathematical equations for the kinetic energy of the system are precisely the same as those given by Maxwell for electric induction.—Dr. S. P. Thompson made a communication on Dr. Kœnig's researches on the physical basis of music, in the course of which Dr. Kœnig performed numerous novel and interesting experiments, clearly illustrating the subject to a crowded audience. After referring to the classical researches of the great mechanician, and to the remarkable precision with which his ingenious and unique acoustical apparatus is constructed, Dr. Thompson said the subject with which he wished to deal could be divided into two parts, the first relating to *beats*, and the second to the *timbre* of sounds. On the question of beats considerable discussion had taken place as to whether they formed independent tones if they were sufficiently rapid. Different authorities had come to different conclusions on the subject, the disagreement probably arising from the impure tones used in their investigations. Dr. Kœnig, however, had succeeded in making tuning-forks whose sounds are very nearly pure tones, and by the aid of such forks had conclusively answered the question in the affirmative. Before proceeding to show experimentally the truth of the conclusions arrived at, Dr. Thompson said it was necessary to define exactly the meaning of the term "harmonics." By this he meant tones whose frequencies are *true integral multiples* of their fundamental. This, he said, might seem to be identical with the "upper partial tones" of Helmholtz or the "overtones" of Tyndall, but such was not the case, as the upper partial tones of piano-wires, &c., are not true integral multiples of the fundamentals, for the rigidity of the wire comes into play, and prevents the subdivision being exact. According to Helmholtz's theory, two tones harmonize when they do not produce beats of sufficient slowness to grate upon the ear, and the frequency of the two sets of beats were supposed to be equal to the difference and the sum of the frequencies of the two fundamental tones. In investigating the subject, Kœnig finds it necessary to distinguish between primary and secondary beats, and also that primary beats belong to two categories. These categories he calls "inferior" and "superior" respectively, and the frequencies of the two sets correspond respectively to the positive and negative remainders obtained by dividing the number representing the number of vibrations in the tone of lowest pitch into the corresponding number for the higher tone. For example, two forks of 100 and 492 vibrations produce beats having 92 and 8 as their vibration frequencies, for

$$492 = 100 \times 4 + 92,$$

and also

$$492 = 100 \times 5 - 8.$$

A set of "superior" beats of 8 per second and an "inferior" beat-tone of 92 per second may be heard when two such forks are sounded together. These primary beats or beat-tones act as independent tones and produce secondary beats. Tertiary ones may also be obtained. To demonstrate the existence of beats to the large audience assembled, Dr. Kœnig had provided two large tuning-forks with resonators about 4 feet long. One of the forks gave 64 vibrations per second, and the other 128, but the latter had sliding weights, whereby its frequency could be made anything between 128 and 64. Adjusting the weights so as to give 72, and bowing both forks, the beats of about 8 per second were distinctly heard at the extremity of the room. By varying the weights so that the fork gave 80, 85⅓, 96, 106⅔, 112, 120, and 128 vibrations successively, beats of various frequencies were produced, and it was remarkable to note that tones of 64 and 120 produced 8 beats a second exactly like 64 and 72. When the forks made 64 and 96 vibrations—*i.e.* at an interval of a fifth—then the inferior and superior beats agree in frequency, viz. 32, and by careful observation a low tone of about this pitch could be heard. If the tones sounded simultaneously differ by more than an octave, the same law for the numbers of beats holds good, whilst Helmholtz's difference and summation tones law, is inapplicable. This was shown by sounding a fork and its double octave slightly mistuned by weighting; slow beats were quite evident, although the difference in the frequencies of the primary notes was large. Similarly forks vibrating approximately at rates in the proportions 1 : 5 and 1 : 6 gave slow beats. Coming to the main question, as to whether beats when sufficiently rapid blend into tones just as primary shocks do, Dr. Thompson briefly recalled the various arguments for and against such an effect, and then Dr. Kœnig proceeded to experimentally prove the affirmative. Taking two forks tuned to 2048 and 2304 vibrations respectively (ratio 8 : 9) and sounding them simultaneously, the middle C of the piano (256) was distinctly heard. The same beat tone resulted from forks having frequencies in the ratio of 8 : 15, whose negative remainder was 256. Various other tones were sounded simultaneously in pairs, and in all cases the corresponding beat-tone was quite distinct. In these experiments the existence of nodes and loops in air was particularly noticeable, for as Dr. Kœnig turned the tuning-forks in his hand, the intensity of the beat-tones heard at a particular spot varied enormously. The experiments were carried a step further by impressing vibrations of different frequencies on one and the same body: the beat-tones in this case were quite perceptible. In carrying this out, Dr. Kœnig had constructed steel bars of approximately rectangular section, whose periods of vibrations were different in two directions at right angles. Striking one face of the bar a certain note resulted, whilst a blow on an adjacent face produced a different one. When the bar was struck on the edge joining the two faces, both the notes could be heard as well as the beat-tone resulting therefrom. The experimenter had gone still further, and made such bars so short that neither of the fundamental notes are within the limits of audition, but the resulting beat-tone can be heard quite distinctly. In all cases the frequency of the beats agrees with that calculated from Dr. Kœnig's formula, and secondary beats follow the same law. It was then pointed out that not only beats, but the maxima of a series of pulsations varying in intensity will, if isochronous and sufficiently rapid, give tones, just as a series of primary shocks do. This was illustrated by tuning-forks, and by directing a stream of air issuing from a slit against a notched rim of a rotating disk. A further confirmation was given by a modified disk siren; in this the holes, instead of being of the same size all round a circle, increase to a maximum and then decrease again, there being several sets of such holes in one circumference. When this was put in operation, notes corresponding in pitch to the number of holes and also to the number of sets of holes,

could be heard. A wave siren was also used to illustrate the same fact. The matter was further illustrated by moving a tuning-fork towards a wall or other reflecting surface at various velocities. According to Doppler's principle, as the fork recedes from the observer and approaches the wall, the frequency of the direct waves is less and that of the reflected waves greater than that of the fork, and these two series of waves produce beats. By sufficiently increasing the velocity and using a fork of high pitch, the beats blend into tones. Coming to the second half of Dr. Kœnig's researches, Dr. Thompson said that Helmholtz contended that the *timbre* of musical sounds was not affected by differences of phase amongst the component tones; on this point, however, Kœnig had come to the opposite conclusion. To illustrate graphically why phase should affect *timbre*, a number of diagrams were exhibited, some showing the resultant wave-form produced by combining a tone with its harmonics of equal intensity, when the differences of phase between them were 0, ¼, ½, and ¾ respectively; whilst others represented the wave-forms when the harmonics and the fundamental were of different intensities. The effect of phase on the shape of the wave-form was very marked. The subject was treated experimentally by means of a wave siren, against which a stream of air issuing from a slit could be directed. By inclining the slit to one side of the radius or the other, the phases of the component waves could be altered, and this had a marked effect on the character of the sound produced. Illustrations of Kœnig's multiple wave sirens, both of the cylinder and disk forms, were next shown, and the results of investigations made with the apparatus described. From these results it appears to be impossible to produce the *timbre* of instruments such as trumpets, clarionets, &c., by any combination of a tone and its pure harmonics. This led to the investigation of impure harmonics. By plotting and combining curves it was shown that the wave-form obtained from a tone and impure harmonics changes in successive periods; this peculiarity was observed to exist in a record taken from a vibrating string. Various disks with wavy edges of different form were spun before an air slit, and the varying character of the resulting sounds as the slit was turned, demonstrated. Before concluding, Dr. Thompson remarked that the word "*timbre*" requires to be re-defined, for the rigidity of strings, wires, &c., and the interference of the wood and metal parts of organ pipes and other wind intruments generally, prevent the formation of pure harmonics. A model consisting of vibrating strips placed vertically or inclined was exhibited to show the different kinds of *timbre*. The differences between mixtures and compounds of tones was pointed out, and the inability of the ear to distinguish between pure and impure sounds referred to. Lord Rayleigh thought more information was required on the important subjects brought forward, and asked in what class of musical sounds are the overtones strictly harmonious. He could admit that in piano wires they may not be so, but he was not quite so clear about organ pipes. He said he was filled with admiration by the perfection of the apparatus displayed, and expressed a wish that such mechanical acousticians could be found on this side of the Channel. Mr. Bosanquet said he had been carefully over the ground investigated by Dr. Kœnig. He believed Dr. Kœnig was the first to get at the facts concerning beats, but it was difficult to admit all that had been said about them. However, the chief difference between authorities seemed to be one of language. Owing to the lateness of the hour he could not discuss the question fully, and so asked to be allowed to reserve his opinion on the matter. As regards *timbre*, he thought the experiments on the effects of phase were not conclusive. The sounds of wind instruments such as trumpets, he said, depended greatly on who produced them. It was no easy matter to bring out their full sweetness, and it was comparatively few persons who could ever attain perfection. He ventured to think that in a properly used instrument none of the harmonics are out of tune. Mr. Blaikley agreed with Lord Rayleigh about piano wires, and as regards wind instruments he could hardly think that the overtones were so inharmonious as Dr. Thompson would have him believe. In fact, Mr. Stroh had obtained wave-forms for him from various instruments, but in none of them was there any discontinuity such as shown on one of the diagrams exhibited. However, he was of opinion that there is something in *timbre* not accounted for by the ordinary theory. The President said that in view of the production of audible sounds by the beats from notes beyond the range of audition, it might be possible to demonstrate that insects produce sounds inaudible to the human ear by putting several together in a box, and listening for the beat-tones. Dr. Kœnig acknowledged the most cordial vote of thanks accorded to himself and Dr. Thompson.

Zoological Society, June 3.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May 1890, and called special attention to a pair of Hartebeests (*Alcelaphus caama*), and a pair of Swainson's Long-tailed Jays (*Calocitta formosa*), acquired by purchase; and to a pair of Beatrix Antelopes (*Oryx beatrix*), presented by Colonel E. C. Ross, Consul-General for the Persian Gulf.—Mr. Sclater exhibited and made remarks on two young specimens of Darwin's Rhea (*Rhea darwinii*), obtained by Mr. A. A. Lane in the province of Tarapacà, Northern Chili, and forwarded to Mr. H. H. James.—Mr. Sclater exhibited and made remarks on a flat skin of a Zebra, received from Northern Somaliland, which appeared to be referable to Grévy's Zebra (*Equus grevyi*).—Mr. A. D. Michael read a paper on a collection of non-parasitic *Acarina* lately made in Algeria, where he had found the *Acarina* less abundant than in England, and, indeed, almost absent from the true southern vegetation. The species met with were not of larger size than the British. The collection consisted almost entirely of Oribatidæ, and contained examples of 46 species belonging to 15 genera. Amongst them were 8 species new to science, 27 were British, and the rest South European. Amongst the new species were a remarkable new *Cæculus*, there being previously only one known species of this curious genus, which forms a separate family. There was also a new *Notaspis*, which had not been found in Europe, but had been received from the shores of Lake Winnipeg, in Canada. There were likewise some very singular new species of the genus *Damæus*, and a triple-clawed form of *Nothrus anauniensis*.—Mr. Frank E. Beddard read a paper on the anatomy of the Fin-foot (*Podica senegalensis*). The paper dealt chiefly with the myology and osteology of this doubtful form. The conclusion arrived at was that it showed most resemblance to the Rails, but that in its muscular anatomy it agreed in many particulars with the Grebes and Divers.—Mr. O. Thomas read some notes on the specimens of Mammals obtained by Dr. Emin Pasha, during his recent journey through Eastern Africa, as exemplified in the specimens contained in two collections presented to the British Museum and the Zoological Society respectively.—Mr. G. A. Boulenger read a paper containing the descriptions of two new species of the Siluroid genus *Arges*, from South America.—A communication was read from Mr. James Yate Johnson, containing descriptions of five new species of fishes from Madeira.

Linnean Society, May 24.—Anniversary Meeting.—Mr. W. Carruthers, F.R.S., President, in the chair.—The Treasurer presented his Annual Report, duly audited; and, the Secretary having announced the elections and deaths of Fellows during the past year, the President proceeded to deliver his annual address. In this he dealt with the distribution of British plants both before and after the Glacial period, making special allusion to the discoveries of Mr. Clement Reid amongst the vegetation of the Cromer Forest Bed, and showed that the forms which have come down to us at the present day do not differ in any respect from the same species found in the Glacial beds.—A vote of thanks was moved by Sir Joseph Hooker and seconded by Mr. Stainton to the President for his excellent address, with a request that he should allow it to be printed, and carried unanimously.—On a ballot taking place for new Members of Council, the following were declared to be elected:—Dr. P. H. Carpenter, Dr. J. W. Meiklejohn, Mr. E. B. Poulton, Mr. D. Sharp, and Prof. C. Stewart. On a ballot taking place for President and Officers, the following were declared to be elected:—President: Prof. Charles Stewart. Secretaries: B. D. Jackson and W. P. Sladen. Treasurer: Frank Crisp.—The Linnean Society's gold medal for the year 1890 was then formally awarded and presented to Prof. Huxley for his researches in zoology.

Entomological Society, June 4.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—The Secretary exhibited, on behalf of Mr. J. Edwards, Norwich, two specimens of *Ilybius subæneus*, Er., and a single specimen of *Bidessus unistriatus*, Schr. Mr. Champion alluded to the fact that the only recorded British specimens of the first-mentioned beetle had been taken many years ago at Peckham. Lord Walsingham, in alluding to the exhibit, referred to the list of Norfolk

Coleoptera compiled some years ago by Mr. Crotch, which appears to have been lost sight of.—Mr. McLachlan alluded to the damage done by insects to orange-trees in Malta, and stated that the Rev. G. Henslow had lately been studying the question; one of the chief depredators was the widely-spread "fly," *Ceratitis citriperda*, well known as devastating the orange. He found, however, that another and more serious enemy was the larva of a large Longicorn beetle (*Cerambyx miles*, Bon.), which bores into the lower part of the stem and down into the roots, making large galleries; in all probability the larva, or that of an allied species, is the true *Cossus* of the ancients. Lord Walsingham stated that a species of *Prays* allied to *P. olcellus* and our common *P. curtisellus* was known to feed in the buds of the orange and lemon in Southern Europe.—The following papers were communicated, and were read by the Secretary:—Notes on the species of the families *Lycidæ* and *Lampyridæ* contained in the Imperial Museum of Calcutta, with descriptions of new species, and a list of the species at present described from India, by the Rev. H. S. Gorham.—A catalogue of the Rhopalocerous Lepidoptera collected in the Shan States, with notes on the country and climate, by Dr. N. Manders, Surgeon, Medical Staff. The latter paper contained a very interesting description of the chief physical features of the Shan States and neighbouring parts of Burmah.

Mathematical Society, June 12.—J. J. Walker, F.R.S., President, in the chair.—The President announced that the Council had unanimously awarded the De Morgan Memorial Medal to Lord Rayleigh, Sec.R.S., for his writings on mathematical physics.—The following papers were read:—On simplicissima in space of n dimensions (third paper), by W. J. C. Sharp.—Rotatory polarization, by Dr. J. Larmor.—Parabolic note, by R. Tucker.—Prof. Greenhill, F.R.S., communicated a paper by Prof. Mathews on the expression of the square root of a quartic as a continued fraction, and one by R. Russell on modular equations.—The President gave a brief sketch of a paper by A. R. Johnson, on certain concomitants of a system of conics and quadrics, and on the calculation of the covariant S of the ternary quartic.

PARIS.

Academy of Sciences, June 9.—M. Hermite in the chair.—On the movement of a prism, resting on two supports, submitted to the action of a variable normal force following a particular law, applied at a determined point of the axis, by M. H. Resal.—Theory of the state produced near to the wide opening of a fine tube where the threads of a liquid which flows there have not acquired the normal inequalities of velocity, by M. J. Boussinesq.—Action of the alkalies and alkaline earths, alkaline silicates, and some saline solutions on mica: production of nepheline, sodalite, amphigene, orthoclase, and anorthite, by MM. Charles and Georges Friedel.—On the fauna of deep parts of the Mediterranean around Monaco, by the Prince of Monaco. Some dredging operations carried on at various depths up to 1650 metres show that, at certain parts at least of these regions, the Mediterranean Sea is by no means devoid of inhabitants as has been previously asserted.—Observations of Brooks's comet (a 1890), made with the *coudé* equatorial of Algiers Observatory, by MM. Rambaud and Renaux. The observations of position extend from May 10 to 31.—Photographic observation of Brooks's comet made at Algiers Observatory, by M. Ch. Trépied (see "Our Astronomical Column").—On a particular case of the movement of a point in a resisting medium, by M. A. de Saint-Germain.—Propagation of light in gold-leaf, by MM. Hurion and Mermeret.—On the amplitude of the diurnal variation of the temperature, by M. Alfred Angot. The author shows how the diurnal temperature variation in any station on the earth may be expressed by the formula—

$$a = \frac{K}{r^2}(A + B \sin l + C \cos 2l),$$

in which K is a function of cloudiness, and = 1 when the sky is clear, A, B, and C are coefficients depending only upon the geographical position of the station and its climatological characters, l the sun's longitude, and r the distance of the earth from the sun.—Electrolysis of fused aluminium fluoride, by M. Adolphe Minet. The author finds a mixture of 40 parts of the double fluoride of aluminium and sodium with 60 parts of sodium chloride to give him the best results yet obtained.—On the isomeric states of chromium sesquibromide: the blue sesquibromide, by M. A. Recoura. A method of preparing the solid hydrated bromide, $Cr_2Br_6, 12H_2O$, corresponding to the violet solutions is given. It is shown that the grey-blue solid obtained is less stable than the green crystals formerly described, whereas the violet solutions corresponding to the blue solid salt are more stable than the green solutions; thermochemical data are given in confirmation.—On the estimation of zinc in the presence of iron and manganese, and its separation from those metals, by M. J. Riban. The zinc is separated as sulphide from a solution to which has been added an excess of sodium thiosulphate.—On the composition of clays and kaolins, by M. Georges Vogt.—On the synthesis of the fluorides of carbon, by M. C. Chabrié.—On the products of saccharification of amylaceous matters by acids, by M. G. Flourens.—On the decomposition of organic manures in the soil, by M. A. Muntz.—On the anatomy of horny sponges of the genus *Hircinia*, and on a new genus, by M. H. Fol.—On the circulatory system in the carapace of decapodous Crustacea, by M. E. L. Bouvier.—On two new species of Coccidia, parasitic on the stickleback and sardine, by M. P. Thélohan.—Interesting nuclear modifications of the nucleolus which may ultimately throw some light on its signification, by M. E. Bataillon.—On a hymenopterous insect injurious to the vine, by M. E. Olivier.—On the diversities and similarities in some dentary systems of mammifers, by M. Heudes.—Researches on the development of the seminal integuments of Angiosperms, by M. Marcel Brandza.—On the nature of the phosphate beds of Dekma (département de Constantine), by M. Bleicher.—On the existence of marine deposits of the Pliocene age in the Vendée, by M. G. Vasseur.

ZOOLOGICAL GEOGRAPHY.

La Géographie Zoologique. Par le Dr. E. L. Trouessart. Avec 63 figures intercalées dans le texte et deux cartes. (Paris: J. B. Baillière et Fils, 1890.)

DR. TROUESSART, author of a "Catalogue des Mammifères Vivants et Fossils," and until recently Curator of the Museum at Angers, has enriched the Bibliothèque Scientifique Contemporaine with a most interesting and valuable book on zoological geography. This work must have caused its author a great amount of labour, to judge from the painstaking way in which he has worked in the facts collected by numerous specialists. Their results, and those of his many predecessors in the fascinating field of the distribution of animals, have been augmented by his own views, and have been condensed into a form which it is agreeable and easy to read.

The first six chapters are devoted to a description of the various zoo-geographical regions as they are now generally accepted. The different types of animals which are to serve as a basis for the investigation of the laws of geographical distribution are grouped in four classes, according to their means of dispersion and their usual habitats: terrestrial, fresh-water, aërial—*i.e.* provided with wings—and marine. The author has greatly increased the value of his book by the graphic method he has employed to show the distribution of given groups of creatures.

The general scheme is given on p. 175, the eight regions into which the author divides the globe being indicated by blocks, which are arranged and connected with each other as follows:—

Arctic Region
| |
Palæarctic Region   Nearctic Region
| |
Ethiopian Region—Oriental Region   Neotropical Region
Australian Region
Antarctic Region.

The *mammalian distribution*, when expressed by such a lucid scheme, comes out thus:—

Arctic

Holarctic [1]
|
Ethiopian   Neotropical
Australian
Antarctic.

This indicates that, so far as mammals only are concerned, the Palæo- and Nearctic regions are practically one, while the Oriental is merged in the Ethiopian region. Australia stands, of course, alone; but that this continent must have been once connected with the Indo-Malayan countries is strongly indicated by the dingo and several other, chiefly rodential, placental mammals in Australia. The discovery by Prof. MacCoy of fossil bones of the dingo in Pliocene strata of Victoria disposes at once of the hypothesis of its having been introduced by man.

The distribution of *reptiles* (p. 204 *f*) is almost entirely based upon G. A. Boulenger's results, as published by him in the "Catalogue of Lizards and Tortoises in the British Museum," and shows to what valuable account such a publication can be turned if worked out upon a proper basis:—

(Palæogæa)   (Neogæa)
Occidental + Oriental   Nearctic Region
+   +   +
African   Australian and Polynesian Regions   Neotropical Region
|
New Zealand Region.

This scheme indicates that in the distribution of reptiles the principal relationships range vertically, with few or hardly any (except, of course, in Europe and Asia) transverse or longitudinal similarities. The globe is practically divisible into two great regions—namely, into Neogæa and Palæogæa, or into an American, Oriental, and Occidental region, New Zealand being a remote and peculiar appendix of the Oriental portion.

On p. 215 *f*, *terrestrial insects*, especially Coleoptera, are discussed. The two Polar regions possess a few forms only, and need hardly be considered. The Holarctic region, connected by the broad vertical belt of Polynesia and the west coast of both Americas with the Australian, New Zealand, and Patagonian regions, is comparatively poor in Coleopterous types, and the forms which occur have certain resemblances in common. Two large centres of rich development in forms and numbers are the Indo-African or Ethiopian, and the Brazilian or typical Neotropical regions.

Région Microtypique (Nord)
| +
Indo-African Region   Polynesia   Brazilian Region
|
Australia   Patagonia
New Zealand
Région Microtypique (Sud).

The division of the globe into Palæogæa and Neogæa is equally applicable to the *Arachnids*, the differences between Arcto and Notogæa being of by far less importance. Arachnid regions are: (1) Palæarctic, (2) Ethiopian, (3) Oriental, (4) Australian, (5) American. The whole of America has practically an Arachnid fauna from north to south, and it is divisible into eight sub-regions, which do not correspond with those of Wallace. The Ethiopian Arachnid region comprises the whole of Africa south of the Atlas, and Central Arabia; it has therefore been called the Libyan region, since it differs by the whole extent of the Sahara from the Ethiopian region of Wallace. The Oriental and Australian regions are those of Wallace, but the Oriental includes Madagascar and South-Eastern Africa as a sub-region. Certainly, so far as Coleoptera and Arachnida are concerned, Madagascar is much more Malayan than African. The Palæarctic region, as a whole, is that of Wallace, but the four sub-regions are differently arranged—namely, Europeo-Siberian, Hispano-Italian (Western Mediterranean and Canary Islands), Taurian or Eastern Mediterranean, with Asia Minor and the Turanian Steppes,

[1] For Holarctic the more convenient and more correct name of the Periarctic region might be substituted. Holarctic should logically include the Arctic together with its subdivisions. Triarctic, an American term, means, of course, Arctic + Palæo + Nearctic, while Periarctic would indicate what is wanted—namely, the Holarctic minus the Arctic region.—H. G.

and lastly the Manchurian sub-region, which consists of China and Japan.

The scheme which represents, after Boulenger, the distribution of *Amphibia*, strongly indicates their distribution in parallel zones—namely, a northern, equatorial, and southern zone. Australia is obviously American in character, but the Indian region includes the whole of the Malayan islands and even New Guinea.

Palæarctic—Nearctic Region
Ethiopian + Indian Region   Neotropical Region
+
Australian Region.

Concerning *fresh-water fishes*, after Dr. Günther, the diagram shows at a glance that the form of the continents has little influence upon the distribution. There are likewise parallel zones, one of which, the Arctic, contains no fresh-water fishes.

Northern Zone = Palæarctic + Nearctic Region.
Equatorial Zone =
African + Indian (Cyprinoid Section)   Pacific or Australian + Neotropical Region (Acyprinoid Section)
Antarctic Zone = Tasmanian   New Zealand   Patagonian
Sub-regions.

The distribution of *terrestrial mollusks* is that of S. P. Woodward and P. Fischer's "Manuel de Conchyliologie," 1887. The six molluscan regions correspond almost exactly with those of Wallace, with this exception, that the Patagonian or Chilian sub-region is elevated to the rank of a seventh region.

In dealing with the distribution of *flying creatures*, the author rightly draws attention to the circumstance that the recent volcanic outbursts of Krakatăo might have killed all the terrestrial inhabitants with the exception of such animals as could fly to neighbouring islands. Therein lies, according to M. Trouessart, the explanation why the Polynesian islands are inhabited by bats and birds only, some of which are peculiar island forms. But these he considers to be the last survivals of a Polynesian fauna, of which we have now only dispersed members. This is one of those perplexing ideas which, although arrived at by a perfectly logical process of thinking, are nevertheless without any real justification.

For the distribution of *birds* Dr. Reichenow's six zones have been adopted; these zones are widely different from the now time-honoured six regions.

Arctic Zone
Oriental Zone   *Occidental Zone*
Oriental Temperate Region   Occidental Temperate Region
Ethiopian Region   Malayan Region   South American Region
Madagascar Zone   *Australian Zone*
Antarctic Zone.

The Oriental and Occidental zones are, of course, nothing but the Palæo- and Neogæa; the word zone should not be applied to eastern and western hemispheres, but rather to horizontal belts. Dr. Reichenow lays stress upon the idea that the annual migration of European and of Asiatic birds shows their connection with the Ethiopian and Malayan regions; hence their combination into one zone, together with what has been called hitherto the Palæarctic region. Madagascar has been elevated to separate rank, and so have the Arctic and Antarctic zones, so that on the whole the old arrangement (based by Dr. Sclater chiefly upon birds) has been completely altered. Birds are far less cosmopolitan than one might suppose, judging only by the strength of their wings.

The distribution of *Lepidoptera* is rather surprising, because the applied schematic representation shows that there are only three great regions. The New World, from Canada to Cape Horn, stands alone; Africa forms only a sub-region of the large Holarctic region, which includes Canada; while Australia forms a sub-region of the Indian region, which again gradually merges in the eastern half of the Holarctic. These results, however, are based upon the somewhat antiquated conclusions drawn by Koch and Staudinger in 1850.

Holarctic Region
American Region   African Sub-region   Indian Region
Australian Sub-region.

According to the Spanish naturalist, J. Bolivar, the distribution of the Orthoptera, which, being possessed of great power of flight, are given to long migrations, agrees rather with that of a part of the Coleoptera.

Pp. 280 and 281 contain a map of the world, on Mercator's projection, upon which the principal ocean currents are indicated, and by conventional signs the distribution of seals, sea-lions, penguins, and auks. The Spheniscidæ have been carried along the west coast of South America as far north as the Galapagos Islands by the cold Humboldt's current, a circumstance which, by the way, was first pointed out by the late Dr. Watson in his *Challenger* Report on the Spheniscidæ. The Pinnipede genus Macrorhinus follows strange lines across the Pacific Ocean, apparently in conformity with existing currents, but the conclusions as to the original home of these sea-elephants seem somewhat far-fetched. The seal *Pelagius monachus*, until recently considered a chiefly Mediterranean species, is known to occur at the Canaries and at Madeira. Another closely allied species, *P. tropicalis*, Gill, has been discovered at certain lonely islands off Yucatan. But is it probable that this species owes its origin to a small group of the Mediterranean species, which has been carried across the Atlantic, past the numerous Antillean islands, almost to the mainland of Central America, there to be transformed into a new species? Is it not more likely that the occurrence of Mediterranean seals in the Atlantic is due to a formerly wider extra-Mediterranean distribution, especially since remnants of such seals have been found recently in the Furfoz caves near Setubal?

The eleventh chapter deals with the faunas of deep seas, high mountains, coast zones, lacustrine and subterraneous regions.

The twelfth, the last chapter, gives a very short account of the distribution of animals in time. Hardly any types of fossil animals are known to have existed in all regions of the globe. The largest animals enjoyed the most restricted range, both in space and in time. The small size and the early occurrence of mollusks and insects explain their now almost cosmopolitan distribution, while the greater abundance of Tertiary mammals, with their subsequent local extermination, gives the clue to

their present often scattered range. The great divisions of the world into Palæogæa and Neogæa are confirmed by palæontology. Still more marked, however, is and has been the contrast between Arcto- and Notogæa: so that one feels inclined to suppose that the Neogæa is only an exaggerated extension of the Notogæa.

Such is a short outline of the contents of this book, which, we feel sure, everyone interested in the study of geographical zoology or of zoological geography, as the case may be, will be pleased to read.

H. GADOW.

JEVONS AND MILL.

Pure Logic and other Minor Works. By W. S. Jevons. Edited by Prof. Adamson and Harriet Jevons. (London: Macmillan and Co., 1890.)

THE services of the late Prof. W. S. Jevons to logic were so eminent that considerable interest attaches to his minor writings on that subject, which are now collected into a volume. The earlier works, "Pure Logic" and "The Substitution of Similars," which are contained in the first and larger part of the volume, possess, indeed, no more than a historic value. They expound his well-known theory of equational logic, but for all practical purposes they are replaced by the later and more interesting exposition which is contained in the "Principles of Science."

The second part of the volume is a reprint of the articles which Jevons contributed to the *Contemporary* in criticism of J. S. Mill. A short chapter on the method of difference is all that the editors were able to add to them out of the mass of manuscript which the author had in preparation for a systematic criticism. These essays do not add to Jevons's reputation. They are a passionate indictment of Mill's consistency: Jevons thought that "Mill's mind was essentially illogical," and in the name of logic he thought it his duty to undermine the authority of Mill's writings. It may be doubted whether any work of theory could bear such a strain of rigorous verbal precision as Jevons endeavours to impose upon Mill. However, not even the most devoted admirers of Mill would maintain that Mill was a consistent thinker; they would find his merit elsewhere. To them and to others it will seem that Jevons has left behind him a criticism far worthier both of himself and of Mill, in the positive advances which he made upon Mill's doctrines in his own work on the principles of science, in the light which he threw upon the fundamental nature of induction, upon the function of hypothesis, and upon Mill's so-called deductive method.

Among the generation which is now entering upon maturity many persons must have passed through a similar history in their feelings with regard to Mill. They became acquainted with his philosophy in youth, and were carried away by its apparent clearness, its freshness and youthful feeling, its love of truth, its dignity, and the large views it gave them of human thought and human life. It opened to them a new world of thought and feeling. Afterwards, as they reflected upon it, with the help of teachers anxious that enthusiasm should not blunt the edge of their pupils' powers of rigorous thinking, they discovered that it was riddled with contradictions real as well as verbal; was full of doctrines laid alongside of each other without adjustment. By and by, when they recovered from the shock of this discovery, they began to perceive that its very errors were light-giving, that its inconsistencies were due to Mill's large-mindedness, his susceptibility to every side of a subject; that where his reasoning was least rigorous it was often most stimulating, and directed inquiry upon new and truer doctrines; and perhaps they often fell into the paradox of cherishing its errors above its truths. Such persons will be inclined to resent a criticism which contents itself with exposing the obvious contradictions of Mill's philosophy.

It is paying poor respect to a thinker to excuse his want of consistency. But with a writer like Mill, above all others, a mere destructive criticism conveys a positively false impression. It is for any higher purpose of little value, because it fails to point out the real significance of the incriminated doctrines. And this is just the vice of Jevons's attack.

Let it be granted at once that Mill's doctrines of geometrical axioms, of the foundation of induction, of pleasure, contain glaring contradictions. Mill holds that geometrical axioms are derived from experience; but while he admits that there is no such thing in existence as a straight line, he declares that we can reason about straight lines because our ideas of spatial figures exactly correspond to the reality. He declared that all induction rests ultimately, in a syllogistic relation, upon the law of causation, and at the same time that this principle is itself derived from particular inductions by the process of simple enumeration, which he elsewhere stigmatizes as vicious. With a theory of pleasure not different in principle from that of Hume and Bentham, he at the same time asserts a distinction of pleasures in kind. In exposing these contradictions, as well as in pointing out the difficulties of the method of difference, Jevons is completely successful; but in leaving the reader to infer that Mill's doctrines are therefore valueless he omits the most necessary part of the critic's task. Mill distinctly says that the axiom that two straight lines cannot inclose a space represents the limit to which many actual experiences approximate. It is true that he did not solve the ultimate difficulty of the relation to reality of such a limiting proposition—call it a hypothesis, or call it an ideal experiment. But, in spite of the gratuitous inconsistencies he introduces into the argument, Mill's contention remains unassailed that geometrical truths derive their authority from the same source as all other truths. With regard to the basis of induction, a more impartial criticism would have pointed out that Mill failed because he was untrue to himself. His doctrine of the syllogism is one of the most important contributions ever made to logic, but if he had been true to it he would have given to the law of universal causation as major premiss of the inductive syllogism a function like that which he assigns to the major premiss of every syllogism, and both secured the consistency of his whole theory as well as the truth of this particular doctrine. His distinction of pleasures according to kind is impossible on his own theory, its real position in his mind uncertain, and its suggestiveness in any case small; but, with its appeal to the judgment of

the good man, it corresponds to a real fact that pleasures do differ according to the position they occupy in the whole moral order, and that this is reflected in the judgment of good men.

But while Jevons's critical attack is successful in the above points, it fails even of its limited object in the attack on Mill's doctrine of resemblance, which is a mere verbal criticism and a misinterpretation. Mill limits the name of propositions of resemblance to those which explicitly state resemblance, or the particular form of resemblance called equality. But because he shows that attributes, propositions, syllogisms, inductive methods, analogy, all involve resemblance, and the word is used on every page of the discussion of these subjects, Jevons accuses him of contradiction. The fallacy of the criticism is obvious. Though all argument and reasoning may depend on resemblance, they need not be concerned with resemblances as such. Who would say when he feels two similar impressions, and feels them therefore similarly, that he necessarily feels and thinks of their similarity as an explicit relation subsisting between them?

The sketch which Prof. Adamson gives of Jevons's full plan leads to the presumption that the rest of his criticisms would have been of the same kind as those published. As one of the subjects discussed is the theory of the syllogism, and of inference from particulars to particulars, reference may be made to the impartial and sagacious treatment of the same subject in Mr. Bosanquet's "Logic," made by a writer of a very different school from Mill. Those who look to what Jevons effected in political economy and logic will not be able to avoid regretting that he should have felt it his duty to bestow so much of the energies of his fine intellect upon a task for which, except for an acuteness not much greater than that of hundreds of students of Mill, he was disqualified by lacking the most essential requisite of a critic.

S. A.

THE WASHINGTON MEDICAL LIBRARY.

The Index Catalogue of the Library of the Surgeon-General's Office, U.S.A. Vol. X. O—Pfutsch. (Washington: Government Printing Office, 1889.)

IT has always been a pleasure to watch the steady growth of this unique Catalogue, and the pleasure increases when we see it now within four, or at most five, years of its completion with the same accurate finish in detail as when its first volume appeared in 1880. It bears on it throughout the stamp of Mr. J. S. Billing's hand, and the elaborate method of cataloguing both books and all signed journalistic articles under the subject-heading, as well as all the books and republished articles under the author's name also, has been fully justified in its results, and has shown its very high value in these ten volumes. This volume can give some clue to the labour that has been involved in that system by its article on "Periodicals," which has been most justly thought so remarkable, as well as useful, as to have been republished by itself. Room can just be found in 212 large quarto pages for the titles of the medical journals—daily, weekly, monthly, quarterly—and the annual reports not only of hospitals, but of all medical and surgical societies, on many matters touching more or less on professional matters. These amount to some 7250 entries, and some 43,670 volumes. That is a total of medical periodical literature which is not approximately reached by the British Museum, the Bibliothèque Nationale of Paris, or any other library, general or professional, in the world. Of course some thousands of these entries—about half, in fact—do not represent living current publications, but about 3600 may be calculated as the total of current medical periodicals catalogued, using the term periodical in the wide sense that will include such publications as the "*Theriaki*, a Magazine devoted to the interests of the opium-eater," the "*Revue Spirite*, ed. par Allan Kardec," and the "*American Rushlight*, by Peter Porcupine." We do not notice any single continuous periodical that has published more than 314 bound volumes such as are furnished by the *Annales de Chimie*, which has been uninterrupted since 1790. A few old Latin *Annales*, or *Acta*, date back to 1692-6, but do not run to any length.

Looking at them as distributed by the countries of their publication, the largest number of past and current together falls to the United States, viz. about 2000; but it must be admitted that on the whole they are smaller and shorter-lived than their fellows, and are more constantly changing their names, a point which is carefully and usefully noted in the Catalogue. The German Empire has rather more than France, viz. about 1100 to 900; Great Britain about 700, Italy about 450, and so on till we come to Syria with two, and Malta with only one. Among so many it can hardly be feasible to avoid every possible mistake. It is a pity, for instance, to enter two such similar publications as the Transactions of the Royal Medical and Chirurgical Society, and of the Clinical Society, the one under Medical and Chirurgical, and the other under Transactions.

This immense mass of literature, however, gives to anyone who looks into it a very striking impression of all the careful labour that must have been necessary to tabulate all the articles in these so-called periodicals under the subject-headings, as has been done, so that the inquirer under any of the commoner subjects may find himself at any moment referred back to an article in a Dutch paper more than 150 years ago.

The "Pest" is the name chosen under which to group all the ancient and modern accounts of the vague and terrible plagues. Under that heading are to be found four editions of Defoe's classical tract on the Plague of London. The collection under this heading of archæological works well illustrates the energy of the American librarians, and the funds that must have been placed at their disposal, for we find of books printed in the fifteenth century 6 dealing with it, of the sixteenth century 169, and of the seventeenth century 207—of themselves not an easy collection to make in the last 30 years on either side of the Atlantic.

A. T. MYERS.

OUR BOOK SHELF.

Food in Health and Disease. By J. Burney Yeo, M.D., F.R.C.P., Professor of Clinical Therapeutics in King's College, London, and Physician to King's College Hospital. (London: Cassell and Co., 1889.)

A GOOD book on food is greatly wanted, one treating of the varieties of food, and their arrangement in the dietaries of health and disease. In some respects Dr.

Yeo's small work fulfils the requirements of a satisfactory book on the subject. It will be found useful for reference by the busy practitioner, and it contains numerous facts, as a rule clearly stated; and it will perhaps also be found acceptable to the lay public, as, in many parts, the style is more or less popular. The chemistry of food-stuffs is not treated as accurately as it might be. Thus we have "syntonin or muscle fibrin; myosin, from muscle," placed in separate lines as food-stuffs. In the table (p. 10), "casein" (probably a misprint for ossein) is placed under "gelatigenous substances"; and gelatin is itself considered a "gelatigenous" substance. This, it must be confessed, is a somewhat loose way of describing these substances.

Dr. Yeo makes the statement (p. 16) that albumen, together with water and salts, is able "alone to support the vital processes," and can "replace in nutrition the fats and carbohydrates." With this statement most physiologists would disagree. Several more instances of somewhat vague statements might be quoted from the work. Milk is considered by all classical writers on the subject a complete or perfect food; but Dr. Burney Yeo goes further than this, and classes eggs as "the only other complete food afforded by the animal kingdom" (p. 51): "but when regarded in the light of a complete food, the shell must be taken into account" (p. 69). In a second edition of the work, the physiological and chemical portion wants careful revision.

In the discussion of the diet in disease, Dr. Yeo is more at home; and he has set forth the various modes of dietetic treatment of disease in a clear manner. The only fault to be found with this part of the book is that the style is somewhat too diffuse to be of great service to the general practitioner, for whose use the work is evidently chiefly intended. Although we have criticized the loose physiological and chemical statements in Dr. Yeo's work (some of which have been quoted), yet the book will no doubt be found useful by many.

Fifth and Sixth Annual Reports of the Bureau of Ethnology to the Secretary of the Smithsonian Institution. By J. W. Powell, Director. (Washington: Government Printing Office, 1887-88.)

THESE Reports, each of which is presented in a large, well-printed volume, contain the record of much solid and useful work. The first of them—the Report for 1883-84—includes an elaborate paper, by Prof. Cyrus Thomas, on burial-mounds of the northern sections of the United States. This is followed by an essay in which Mr. Charles C. Royce tells the story of the official relations of the Cherokee nation of Indians with the Colonial and Federal Governments of North America. In the third paper, Dr. W. Matthews gives an account of what Prof. Powell describes as one of the most illustrative ceremonies of the Navajo, a tribe formerly widely diffused, and now settled in parts of New Mexico and Arizona. Dr. Clay MacCauley deals with the Seminole Indians of Florida, and Mrs. Tilly E. Stevenson gives a vivid picture of the religious life of the Zuñi child. Of the papers associated with the Report for 1884-85, the first is on the ancient art of the province of Chiriqui, Colombia, by Mr. William H. Holmes. To this excellent paper we have already called attention. It is followed by another, by the same author, on textile art in its relation to the development of form and ornament. Dr. Franz Boas contributes to the volume an instructive and well-arranged paper, in which he sets forth the results of his observation and study of the central Eskimo. Prof. Cyrus Thomas gives some aids to the study of the Maya codices, and Mr. J. Owen Dorsey brings together interesting versions of two Osage traditions. These versions are printed in the original language, with an interlinear and a free translation of each, and with explanatory remarks.

Light, Heat, and Sound. By Chas. H. Draper, B.A. D.Sc. (Lond.). (London: Blackie and Son, 1890.)

THE syllabus of contents of this little work is that of the elementary stage of the Science and Art Department, some additions being made in the sections on light and Heat in order to bring them up to the standard of the London University matriculation paper. Viewed as an examinational text-book, there is much that is meritorious in the arrangement and general character of the work, the information being conveyed in the disintegrated fashion now so common. We would, however, point out to Dr. Draper that hoar-frost is not frozen dew, but water deposited in the solid form, and that hail is not simply rain-drops frozen as they fall through a cold stratum of air. The questions placed as exercises at the end of the chapters have been selected from papers set at the above examinations, and will serve not only as a test of the student's progress, but as a branch of his mental education worth cultivating.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Bourdon Gauge.

ALLOW me to suggest to such of your readers as are interested in this subject the following experiment. Cut out of cardboard two annular strips, each of somewhat more than a quadrant, the inner radius being say 7 inches, and the outer radius 9 inches. Along the middle of each strip—that is, along the circle of 8 inches radius—cut the boards half through, so as to render them flexible, and then join the two strips together with gum paper at the inner and outer edges. In this way we obtain a curved tube whose section is a rhombus, and whose curvature is connected with the magnitudes of the angle of the rhombus. The manipulation of such a tube gives definiteness to one's ideas, and enables one to recognize that internal pressure, tending to augment the included volume, and therefore to make the section square, must also cause the curvature of the axis to approach a definite associated value. In this case the deformations are practically by bending, principally, indeed, at the hinges; and I cannot doubt that in its main features the mechanism of an ordinary Bourdon gauge may be looked at in the same light.

RAYLEIGH.

The Optics of the Lightning Flash.

IN the extract from Mr. Shelford Bidwell's recent lecture on "Lightning" at the London Institution, which appeared in your issue of June 12 (p. 151), I notice the author says that the lightning flash of artists has no existence in nature, and that it is an artistic fiction or symbol. May I venture to trespass on your valuable space to refer to a paper which I had the honour of reading before the Royal Meteorological Society (published in the current Quarterly Journal of the Society) only a few days after the delivery of Mr. Shelford Bidwell's lecture? In this paper I endeavoured to show how the "zigzag" flash so often seen by observers, and frequently depicted by artists, may have its counterpart in nature, quite consistently with the evidence of the photographs of lightning flashes collected by the Royal Meteorological Society.

I suggested that such an appearance is not the flash itself, but the optically projected image of the flash formed on clouds, not of a smooth surface, but of the rocky cumulus type. The image of the flash takes the angles of the uneven surface and becomes zigzagged. I showed how this might be by casting the photograph of a lightning flash—the "streaming" flash—by means of the optical lantern, on model cumulus clouds, made of cotton wool. The "streaming" flash became distorted, and in fact zigzagged, so that it could not have been recognized as the type mentioned.

"Projection" lightning flashes surely must happen in nature, and might be accounted for in more ways than one. I will

mention now one simple way which I illustrated by experiment at the meeting referred to. It is fairly well recognized that sheet lightning is the reflection of a flash on a cloud, for example; but if there happens to be the presence of a cloud with a small opening in it somewhere between the actual flash and the distant surface of clouds, then, instead of "sheet" lightning appearing on the latter, there will be "projection" lightning—that is, the image of the flash, whose shape will depend upon the shape of the cloud on which it is cast.

In speaking of zigzag representations of lightning flashes, it is important to make some distinction between the artistic zigzag and a common pictorial type such as is seen on the covers of electrical books, in dissolving views, in scenic effects, and even in street advertisements. It is hardly fair to saddle the artists with the latter class. A good specimen of an artistic zigzag flash, and one which shows an observance of nature, can be seen in Wilson's famous picture of "Celadon and Amelia."

It certainly seems at first sight strange that the "projection" flash should not be included in the photographs of lightning flashes. Its non-appearance may be due (1) to the photographic plates not being sufficiently sensitive to register a flash of diminished brilliancy, for the projected image of any source of light has not the same intensity as the source itself. (2) The "projection" flash being of rarer occurrence, the number of photographs yet taken may not have included it. If the type is rarer, it may be objected that it is not likely that artists would generally depict a rare type in preference to the more common one; but the less dazzling nature of the "projection" would be sufficient to account for its adoption, rendering the form of the flash more distinct to the average eye. To take an illustration, if an electric arc light is suddenly flashed before our eyes, we fail to distinguish the form of the white-hot carbon points, but if its image were flashed upon a screen, their form would be distinctly visible.

It is worthy of note that some painters have chosen to represent other types than what I have termed the "projection" flash. See Turner's "Stonehenge," where "streaming" lightning is pictured. Eric Stuart Bruce.

The Bagshot Beds of Essex.

In the second part of the paper on the Westleton beds, by Prof. Prestwich, recently published in the *Quarterly Journal of the Geological Society* (vol. xlvi. p. 152), a section of the Brentwood railway cutting is given, which is, if possible, of more interest from the Eocene beds described than from its bearing on the questions dealt with in the paper.

Reading the new section together with what we already know, we get the following succession of beds at Brentwood:—

(1) *Pebble beds*, capping the plateau up to 15 feet thick.

(2) *Bagshot beds*, about 50 feet, consisting of—

(*a*) Yellow or white sands (bed 6 of Mr. Whitaker's section, "Geology of London," i. 274).

(*b*) The green sands and clays *with fossils* of the railway cutting.

(*c*) Yellow sand with seams of clay of the railway cutting.

(3) *London clay*, about 435 feet, the upper part consisting of dark grey clay, with one or more beds of loam and yellow sand, the so-called "passage beds" exposed in the brick-fields near the station.

The fossils which Mr. Herries and I found near Frierning (Whitaker, "Geology of London," i. 276) came from white sand probably answering to bed 2*a*.

This section seems to show pretty clearly that the Bagshot beds of Brentwood are more nearly allied to the marine Bracklesham (Middle Bagshot) series than to the Lower Bagshots of the Bagshot Heath district, which are probably freshwater. If this be so, the masses of pebbles which overlie them may well be the remains of the pebble beds which so often mark the base of the Upper Bagshot (Barton) beds, and the parallel drawn by Mr. Herries and myself between the pebbles which cap the Warley and Brentwood plateau in Essex and those which cap Hook Heath and other hills in the Bagshot district becomes the more marked (Proc. Geol. Assoc., vol. xi. pp. 13, 16, 20).

Electro-Magnetic Repulsion.

Those who have not the means of showing the striking effects produced by Prof. Elihu Thomson may be glad to know a simple illustration of the same principles.

A top consists of a soft iron disk with a brass axis put through it. A small magnet is held over the edge whilst spinning; each elementary sector as it moves up to and away from the poles of the magnet has currents induced which are repelled by the magnet; as the rotation dies out, the currents at a certain point become too feeble to overcome the attraction of the soft iron by the magnet. I bought the top two or three years back of M. Manet, 49 Rue Lourmel, Paris. W. B. Croft.

Winchester College, June 21.

A Remarkable Appearance in the Sky.

There was an appearance in the sky last night, so remarkable that I am tempted to describe it, in case, our situation being high, it should have been better seen here than elsewhere. Along the horizon, from north to about north-east, a faint bank of cloud extended, above which was a space of light like that of the early dawn or of the rising moon. There was no quivering, or shooting upwards of rays, as in the ordinary northern lights; the light was steady, white tending to yellow, brighter at the lower part. Above it hung a purplish haze, through which the stars shone brightly, and occasional strips of dark cloud. It did not happen to be observed till 10.30 p.m., and it was hardly altered at 1.30 a.m., when it was still bright enough to mark the window-frame through a white blind, like moonlight. Besides the position, the fact of a solar eclipse occurring that day proved the moon to have nothing to do with it.

Sussex, June 18. M. E.

PROBLEMS IN THE PHYSICS OF AN ELECTRIC LAMP.[1]

I.

More than eighty years ago Sir Humphry Davy provided the terminal wires of his great battery of 2000 pairs of plates with rods of carbon, and, bringing their extremities in contact, obtained for the first time a brilliant display of the electric arc.[2] The years that have fled away since that time have seen all the marvellous developments of electro-magnetic engineering, have placed in our possession the electric glow-lamp, and brought the art of electrical illumination to a condition in which it progresses each year with giant strides. In addition to the importance attaching to their ever-increasing industrial use, there are many questions of purely scientific interest which present themselves to our minds when we proceed to examine the actions that take place when a carbon conductor is rendered incandescent in a high vacuum, or when an electric arc is formed between two carbon poles. It is to a very few of these physical problems that I desire to direct your attention to-night, but more especially to one which is particularly interesting from the bearing which it has on the general nature of electric discharge.

We know as a very familiar fact that if we attempt to raise the temperature of a carbon conductor inclosed in a vacuum beyond a certain limit, not far removed from the melting-point of platinum, the carbon begins to volatilize with great rapidity. If an electric glow-lamp has passed through its carbon more than a certain strength of current, the glass bulb speedily becomes darkened by a deposit of this volatilized carbon condensed upon it; and experience shows us that we cannot raise the temperature of that carbon beyond a definite point without causing this waste of the conductor to become very rapid. In the highly rarefied atmosphere within the bulb of a glow-lamp, the carbon, when at its normal incandescence, must be con-

[1] Friday Evening Discourse delivered at the Royal Institution by Prof. J. A. Fleming, M.A., D.Sc., on February 14, 1890.

[2] Sir Humphry Davy laid a request before the managers of the Royal Institution on July 11, 1808, that they would set on foot a subscription for the purchase of a large galvanic battery. The result of this suggestion was that a galvanic battery of 2000 pairs of copper and zinc plates was set up in the Royal Institution, and one of the earliest experiments performed with it was the production of the electric arc between carbon poles, on a large scale. It is probable, however, that Davy had produced the light on a small scale some six years before, and, according to Quetelet, Curtet observed the arc between carbon points in 1802. See Dr. Paris's "Life of Sir H. Davy."

sidered to be projecting off molecules of carbon in all directions, partly in virtue of purely thermal actions, but probably also in consequence of certain electrical effects to be presently discussed. This scattering of the material of the carbon conductor takes place with disadvantageous rapidity from an industrial point of view at and beyond a certain temperature,[1] but it exists as well at much lower temperatures than that which is found to determine the practical limit of durability. A curious appearance is found in many incandescent lamps which have been "over-run," which shows us that this projection of carbon molecules from the hot conductor is not, perhaps, best described by calling it a vaporization of its substance, but that the surface molecules are shot off in straight lines, and that they reach the glass envelope without being hindered to any great extent by the molecules of the residual air.

If an electric current is passed through an otherwise uniform carbon conductor, which possesses at any one place a specific resistance higher than that of the remaining portion, the current, in accordance with a well-known law, there develops a higher temperature, and the molecular scattering at that spot may in consequence be greatly exaggerated. It may be that the detrition of the conductor at that locality will be so great as to cut it through after a very short time. When the carbon has the form of a simple horseshoe loop, and when this mole-

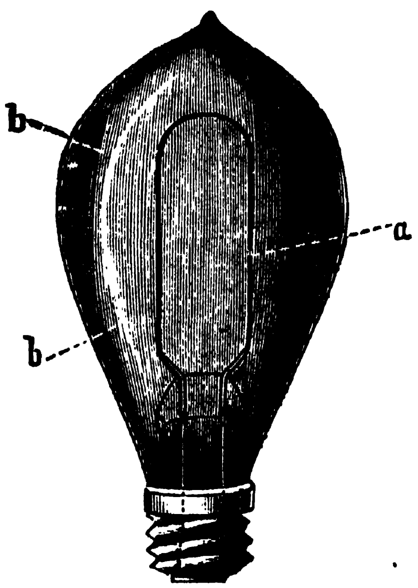

FIG. 1.—Glow-lamp, having the glass bulb blackened by deposit of carbon, showing the molecular scattering which has taken place from the point *a* on the filament, and the shadow or line of no deposit produced at *b*.

cular scattering takes place from some point in the middle of one branch, the molecular projection makes itself evident by producing a "molecular shadow" of the other leg upon the interior of the glass. I will project upon the screen an image of the carbon horse-shoe loop taken from an old glow-lamp, and you will be able to see that the filament has been cut through at one place. At that position some minute congenital defect caused the carbon to have a higher resistance, the temperature at that point when it was in use became excessive, and an intensified molecular scattering took place from that locality. On examining the glass bulb from which it was taken, we find that the glass has been everywhere darkened by a deposit of the scattered carbon except along one narrow line (see Fig. 1), and that line is in the plane of the carbon loop and on the side opposite to the point of rupture of the filament.[2]

[1] When the rate of expenditure of energy in the carbon conductor is raised until it reaches a value of about 500 watts, or 360 foot-pounds per second per square inch of radiative surface, a limit of useful temperature has been reached for economical working, under the usual present conditions of steam-engine-driven dynamos and modern glow-lamps.

[2] The writer desires to express his indebtedness to the editor of the *Electrician* for the loan of the blocks illustrating this abstract.

I may illustrate to you, by a very simple experiment, the way in which that "shadow" has been formed. Here is a ∩-shaped rod: this shall represent the carbon conductor in the lamp; this sheet of cardboard placed behind it, the side of the glass receiver. I have affixed a little spray-producer to one side of the loop, and from that point blow out a spray of inky water. Consider the ink spray to represent the carbon atoms shot off from the overheated spot. We see that the cardboard is bespattered on all points except along one line where it is sheltered by the opposite side of the loop. We have thus produced a "spray shadow" on the board (Fig. 2). The existence of these molecular shadows in incandescent lamps leads us therefore to recognize that the carbon atoms must be shot off in straight lines, or else obviously no such sharp shadow could thus be formed. This phenomenon confirms in a very beautiful manner the deductions of the kinetic theory of gases. I may remind you that at the ordinary temperature and pressure, the mean free path of a molecule of air is deduced to be about four one-millionths of an inch. This is the average distance which such a gaseous molecule moves over before meeting with a collision against a neighbour which changes the direction of its path. Let the air be rarefied, as in these bulbs, to something like a millionth of the ordinary atmospheric pressure, and the mean free path is increased to several inches. The space within the bulb—though from one point of view densely populated with molecules of residual air—is yet, as a fact, in such a condition of rarefaction that a carbon molecule projected from the conductor can move over a distance of three or four inches on an average

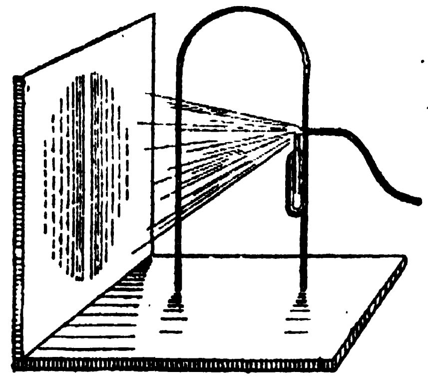

FIG. 2.—"Spray shadow" of a rod thrown on cardboard screen to illustrate formation of "molecular shadow" in glow-lamps.

without meeting with interference by collision with another molecule, and the facts revealed to us by these shadows show that this must be the case. I have also at hand some Edison lamps in which these "molecular shadows" are finely shown, but in these cases the deposit on the interior of the bulb is not carbon but copper, because the molecular scattering has here taken place by excessive temperature developed at the copper clamps by which the carbon filament is attached to the platinum wires. The theory, however, is the same. The deposit of copper shows a fine green colour by transmitted light in the thinner portions. One curious lamp also before me had by an accident an aluminium plate volatilized within the bulb. The glass receiver has in consequence been covered with a mirror-like deposit of aluminium, which on the thinner portions shows a fine blue colour by transmitted light, and a silvery lustre by reflected light. This lamp also shows a fine "molecular shadow."

These facts prepare us to accept the view that when a glow-lamp is in operation the highly rarefied residual air in the interior of the bulb is being traversed in all directions by multitudinous carbon atoms projected off from the incandescent carbon conductor. I now wish to pass in review before you some facts which indicate that these carbon atoms carry with them electric charges, and that they are charged, if at all, with *negative electricity*.

I may preface all by saying that much of what I have to show you will be seen to be closely related to the phenomena studied by Mr. Crookes in his splendid and classical researches on radiant matter. Our starting-point for this purpose is a discovery made by Mr. Edison in 1884, and which received careful examination at the hands of Mr. Preece in the following year,[1] and by myself more recently. Here is the initial experiment. A glow-lamp having the usual horseshoe-shaped carbon (see Fig. 3) has a metal plate held on a platinum wire sealed through the glass bulb. This plate is so fixed that

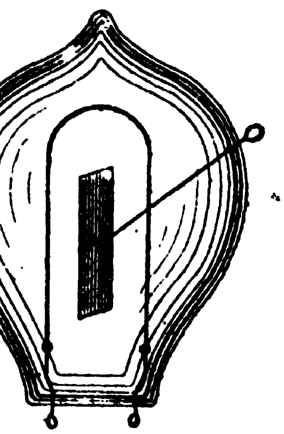

Fig. 3.—Glow-lamp having insulated metal middle plate M sealed into bulb to exhibit "Edison effect."

it stands up between the two sides of the carbon arch without touching either of them. We shall illuminate the lamp by a continuous current of electricity, and for brevity's sake speak of that half of the loop of carbon on the side by which the current enters it as the positive leg, and the other half of the loop as the negative leg. The diagram in Fig. 4 shows the position of the plate with respect to the carbon loop. There is a distance of half an inch, or in some cases many inches, between either leg of the carbon and this middle plate. Setting the lamp in action, I connect a sensitive galvanometer between the

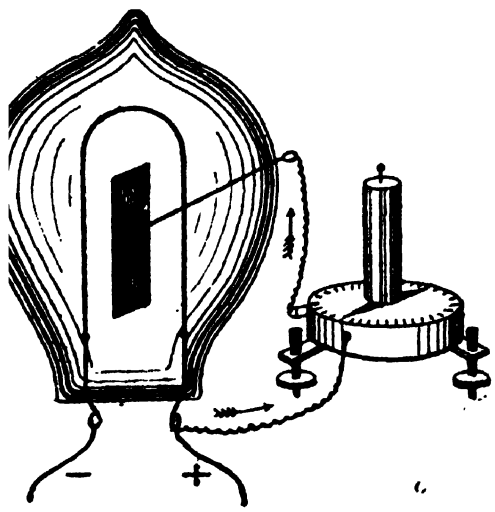

Fig. 4.—Sensitive galvanometer connected between the middle plate and positive electrode of a glow-lamp, showing current flowing through it when the lamp is in action ("Edison effect").

middle plate and the *negative terminal* of the lamp, and you see that there is no current passing through the instrument. If, however, I connect the terminals of my galvanometer to the middle plate and to the *positive electrode* of the lamp, we find a current of some milliamperes is passing through it. The diagrams in Fig. 5 show the mode of connection of the galvanometer in the two cases. This effect, which is often spoken of as the "Edison effect," clearly indicates that an insulated plate so placed in the vacuum of a lamp in action is brought down to the same potential or electrical state as the negative electrode of the carbon loop. On examining the direction of the current through the galvanometer we find that it is equivalent to a flow of negative electricity taking place through it *from* the middle plate *to* the positive electrode of the lamp. A consideration of this fact shows us that there must be some way by which negative electricity gets across the vacuous space from the negative leg of the carbon to the metal plate, whilst at the same time a negative charge cannot pass from the metal plate across to the positive leg. Before I pass away from this

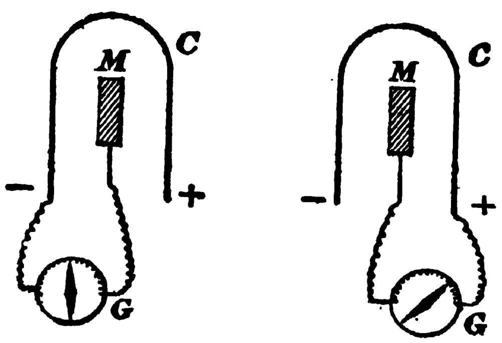

Fig. 5.—Mode of connection of galvanometer G to middle plate M and carbon horseshoe-shaped conductor C in the experiment of the "Edison effect."

initial experiment, I should like to call your attention to a curious effect at the moment when the lamp is extinguished. Connecting the galvanometer as at first, between the middle plate and the negative electrode of the lamp, we notice that though made highly sensitive the galvanometer indicates no current flowing through it whilst the lamp is in action. Switching off the current from the lamp produces, as you see, a violent kick or deflection of the galvanometer, indicating a sudden rush of current through it.

In endeavouring to ascertain further facts about this effect one of the experiments which early suggested itself was one directed to determine the relative effects of

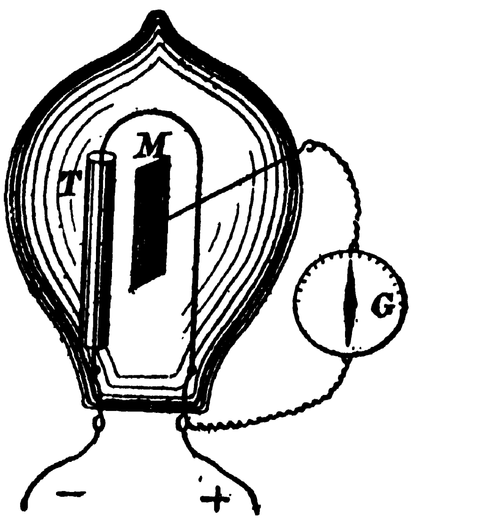

Fig. 6.—Glow-lamp having negative leg of carbon inclosed in glass tube T, the "Edison effect" thereby being annulled or greatly diminished.

different portions of the carbon conductor. Here is a lamp (see Fig. 6) in which one leg of the carbon horseshoe has been inclosed in a glass tube of the size of a quill, which shuts in one-half of the carbon. The bulb contains, as before, an insulated middle plate. If we pass the actuating current through this lamp in such a direction that the covered or sheathed leg is the *positive* leg, we find the effect existing as before. A galvanometer connected between the plate and positive terminal of the lamp yields a strong current, whilst if connected between the negative terminal and the middle plate there is no current at all. Let us, however, reverse the current

[1] Mr. Preece's interesting paper on this subject is published in the "Proceedings" of the Royal Society for 1885, p. 219. See also the *Electrician*, April 4, 1885, p. 436.

through the lamp so that the shielded or inclosed leg is now the negative one, and the galvanometer is able to detect no current, whether connected in one way or the other. We establish, therefore, the conclusion that it is the negative leg of the carbon loop which is the active agent in the production of this "Edison effect," and that if it is inclosed in a tube of either glass or metal, no current is found flowing in a galvanometer connected between the positive terminal of the lamp and this middle collecting plate.

Another experiment which confirms this view is as follows:—This lamp (see Fig. 7) has a middle plate, which is provided with a little mica flap or shutter on one

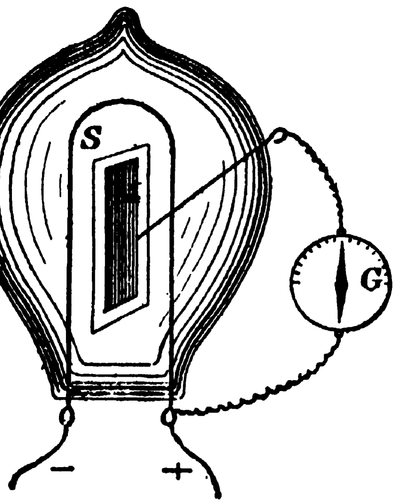

FIG. 7.—Glow-lamp having mica shield S interposable between middle plate M and negative leg of carbon, thereby diminishing the "Edison effect."

side of it. When the lamp is held upright the mica shield falls over and covers one side of the plate, but when it is held in a horizontal position the mica shield falls away from the front of the plate and exposes it. Using this lamp as before, we find that when the positive leg of the carbon loop is opposite to the shielded face of the plate, we get the "Edison effect" as before in any position of the lamp. Reversing the lamp current and making the same leg the *negative* one, we find that when the lamp is so held the metal plate is shielded by the interposition of the mica, and the galvanometer current is very much less than when the shield is shaken on one side and the plate exposed fully to the negative leg.

(*To be continued.*)

SOME EXPERIMENTS ON FEEDING FISHES WITH NUDIBRANCHS.

WITH the view of testing the theory that the remarkable shapes and colours of Nudibranchs are either of a protective or of a warning nature,[1] and are definitely related to the edibility or the reverse of the animals, I have been offering lately various kinds of Nudibranchs to the fishes in the aquarium of the Liverpool Free Public Museum,[2] and have carefully noted the result of each trial.

Although these experiments will have to be repeated, and additional evidence accumulated, still it may be interesting to other biologists working on similar lines to have this account of the inquiry, in its present stage, laid before them, and I need scarcely say that I would be glad of any suggestions which would be useful in future investigations.

Most of the experiments were made in three large fish-tanks, which may be called A, B, and C. A and B are rectangular slate and plate-glass wall-tanks, lit from the top, measuring 7½ feet long, 5¼ feet wide, and 3¼ feet high. A has a gravel bottom, and contains about 20 very healthy and active shannies (*Blennius pholis*) obtained from the Menai Straits; while B has a sandy floor, and is devoted to flat-fish. It contains a considerable number of soles and plaice, a few small thornback rays, turbot, and brill, and on one of the occasions had some young cod. The average size of these flat-fish is 6 inches in length, and there are over 60 of them in the tank. Both A and B have some rock-work. C is an octagonal centre-tank with a sandy bottom, measuring 4½ feet in diameter, and 17 inches in depth. It contains various small fishes, viz. bullhead, goldsinny, pogge, gemmeous dragonet, five bearded rockling, viper-weever, and young cod.

All these fishes are apparently in a healthy condition, and some of them have been living undisturbed in their tanks for periods varying up to four years. They are usually fed upon mussels, cockles, and occasionally worms, which are thrown in at the top of the tank and allowed to sink through the water. Such food-matters are usually seen at once, and eagerly pounced upon and eaten during their descent. I adopted the same plan in putting most of the Nudibranchs into the tanks, and as the fishes were not fed on the days I intended to experiment with them, and had usually been fasting for 24 hours when I began, they may be regarded as being unusually eager to seize any object dropped into the water. At the beginning and again at the end of each day's experiments, we threw a couple of cockles or mussels into the tanks, and found that they were at once caught and bolted in the usual manner.

I. *October* 29, 1889. [A supply of *Doris*[1] *bilamellata* was obtained from the rocks at New Brighton.]

TANK A.—*Doris.*

(1) Seized, when falling, by a shanny, and taken at once to dark corner.

(2) Seized and at once rejected, seized by another shanny and at once rejected, seized by a third and rejected, then allowed to lie on bottom of tank.

(3) Seized and rejected by two fish in rapid succession, then seized by third and taken to dark corner.

(4) Seized and rejected by first fish, taken to dark corner by second.

(5) Seized and rejected by three fish in rapid succession, and then left.

TANK B.—*Doris.*

(1) Seized and rejected in rapid succession by a turbot, a sole, another sole, and a plaice, and then left lying on the sand.

TANK C.—*Doris.*

(1) Seized and rejected by a goldsinny, tried again by same and again rejected, then left.

(2) Seized and rejected by a bullhead and by a dragonet in rapid succession, and then left.

Finally, another *Doris* was dropped gently into a fourth tank containing a conger eel, so as to fall in front of its nose; but although the fish passed close to the Nudibranch several times while under observation, it apparently took no notice of it.

From these nine experiments it seems probable that *Doris bilamellata* is distasteful to at least most of these eight kinds of fishes tried. This was an unexpected result, as *Doris* has no stinging apparatus, and certainly seems to be protectively coloured. The distastefulness may be due to the spicules in the skin or to the abundant mucus covering the body.

[1] *Quart. Journ. Microsc. Sci.*, vol. xxxi. p. 41.
[2] With the kind permission and assistance of Mr. T. J. Moore, the curator, and his assistants, who were present at all the experiments.

[1] I use throughout this article the old well-known generic names *Doris* and *Eolis*, instead of the modern genera, only known to specialists, in which the species I am dealing with have been placed. No possible confusion can arise from doing so.

II. *February* 21, 1890. [Large supply of *Ancula cristata*, and a few *Dendronotus arborescens*, *Eolis rufibranchialis*, and *Eolis picta* from Hilbre Island.]

Mr. Moore and I each ate an *Ancula*. The specimen was placed alive upon the tongue. No stinging or other disagreeable sensation was perceived. It was then chewed slowly and swallowed. The taste was pleasant, and distinctly like that of an oyster.

TANK A.—*Ancula.*

(1) Seized and rejected by a shanny, and then bolted suddenly by a second.

(2) Seized and rejected by ten fish in rapid succession.

(3) Seized, when falling, and swallowed by a fish.

(4) Seized and rapidly rejected by five fish in succession.

(5) Seized and rapidly rejected by four fish in succession.

TANK B.—*Ancula.*

(1) Seized and rejected by a young cod and six plaice in rapid succession.

(2) Seized and rejected by seven plaice, and left lying on sand.

(3) Seized and rejected by four plaice, and left lying on sand.

The fish were then tried with some cockles, which, when thrown in, were eagerly pounced upon and eaten.

(4) Then four specimens of *Ancula* were dropped in together, and were tried and rejected by two young cod and three plaice.

TANK C.—*Ancula.*

(1) Touched by a young cod, but not taken, then tried and rejected by goldsinny.

(2) Touched and rejected several times by young cod.

(3) Touched and rejected by first cod, bolted suddenly by second.

The shannies at once take an object into the mouth, even though they reject it again immediately, but the young cod usually approach it very closely, and appear to smell it or feel it with the lips, and then turn away from it, or else suddenly bolt it, in which case it does not reappear. The shanny seems to test the edibility inside its mouth, the cod outside.

Some crabs (*Hyas araneus*) in two small tanks were then tried with specimens of *Ancula* with the following results:—

(1) Seized at once by crab, but eaten very slowly, and only partially.

(2) Taken no notice of.

(3) Taken up with chela, then dropped and left.

(4) Apparently not noticed by crabs.

The three last specimens of *Ancula* were found alive and fully expanded next day, and crawled about the two crab tanks undisturbed for some time afterwards.

Finally, a few specimens of *Ancula* were offered to two large anemones (*Actinoloba*), but were not taken.

In all, then, *Ancula* was rejected by 53 animals and taken by four. These experiments gave us the distinct impression that *Ancula* was distasteful to the animals tried, although we did not at that time understand why, and had expected to get a contrary result.

TANK A.—*Dendronotus.*

(1) Seized at once by shanny, and carried off to back of tank; shortly afterwards two shannies were found fighting over it, each having hold of an end, as they do with a large worm; finally, they each ate a part of the *Dendronotus*.

TANK B.—*Dendronotus.*

(2) Tried and rejected by brill and young cod. Then seized by plaice and kept in mouth for a long time (five to ten minutes), during which it was pursued by other fish.

TANK C.—*Dendronotus.*

(3) Touched and left by young cod; taken partly into mouth and rejected by two bullheads four or five times.

The general impression we received was that *Dendronotus* was more acceptable to the fish than *Ancula*, but that they were incommoded by the size. Our specimens were large ones—over two inches in length—and none of the fishes tried seemed able to get the whole of the *Dendronotus* comfortably into the mouth, at once. Several took half the body into the mouth, and swam about with the other half hanging out. This was well seen in the case of the two shannies, who each ate half of the specimen, and of the plaice which carried about its prey for a considerable time, during which it was actively pursued by the others. That specimen was in all probability eaten by one or more of the plaice, as we could not find any trace of it a short time afterwards. The rejection by the bullheads may be accounted for by the awkward size of the morsel. The two fish had each at least two tries at it, taking it half into the mouth, giving it a shake, sending it out, and then going at it again as if to get a better hold.

TANK A.—*Eolis.*

(1) Seized by largest shanny, who at once shook it vigorously, and kept moving its jaws and ejecting the cerata[1] in groups of three or four, and finally put out the rest of the body. Then tried and rejected by four or five other fish in rapid succession, and then by the large shanny again, then by several others, and finally left lying on the bottom. The large shanny who first tried it was going about for some time afterwards with the mouth held open.

TANK C.—*Eolis.*

(2) Touched or tried, and rejected at once by cod, bullhead, and weever. The cod came very near it, or touched it with its snout, several times afterwards, but never took it into the mouth.

Eolis is undoubtedly distasteful. The cnida (stinging cells) on the tips of the cerata probably sting the lips of the fish. As it had occurred to me that the natural conditions would be more nearly reproduced if the Nudibranchs were not dropped into the tanks, on the following day, February 22, a few specimens of *Ancula* were placed upon pieces of stone and lowered cautiously into tanks A and B in such a way as not to attract the attention of the fish. The Nudibranchs reached the rockwork safely, and were seen crawling over various parts of the tanks for several days untouched by the fish (shannies and flat-fish). Woods, the aquarium attendant, tells me that the fish sometimes went up close to the *Ancula*, and looked at them, but never attempted to touch them. The Nudibranchs were last seen about a week after being put into the tanks. They then disappeared, but may possibly have retreated into the back part of the tank, or have crawled up out of the water, as *Ancula* is very liable to do when kept in captivity.

III. *March* 22, 1890. [*Dendronotus*, *Eolis*, and *Doris* from Hilbre Island.]

TANK A.—*Dendronotus.*

(1) Seized at once by the large shanny and kept in the mouth, half the Nudibranch projecting. This shanny was pursued by others, one of which caught the projecting end of the prey, and in the ensuing struggle tore half the body off and ate it. The large shanny at once retreated with the remainder to the back of the tank, came out shortly afterwards with the *Dendronotus* still in mouth, and was again pursued and retreated to the dark, appearing again soon without the Nudibranch.

[1] The coloured dorsal papillæ which contain the stinging cells.

TANK C.—*Dendronotus.*

(2) Pounced upon at once by three bullheads (*Cottus*), which made rapid dabs at it successively, until one secured it and carried it off to a quiet place, where he seized it in his mouth and ejected it nine times in succession, each time taking it half into the mouth and keeping it there for some seconds, then spitting it out and at once pouncing upon it again. Finally, the now somewhat mangled remainder of the *Dendronotus* was taken out and put into tank A, where one of the shannies at once seized and swallowed it. This *Dendronotus* was large. It was larger than the head of the *Cottus*, and caused the mouth-cavity to bulge out greatly when it was taken in. The general impression was that the *Cottus* found the *Dendronotus* desirable food, but an uncomfortably large mouthful, and was trying to worry it to pieces.

TANK A.—*Eolis.*

(1) Tried, and at once rejected by three shannies in rapid succession, then seized by the large shanny and carried behind some rock-work. Immediately, numerous red cerata were seen scattered through the water in that neighbourhood, showing that the *Eolis* had been forcibly ejected in pieces. The cerata floated about for some time in the water, but were not touched by any of the fish.

(2) Pounced upon by several fish together; one secured and at once rejected it, and then, seizing the white body, managed to bite it across, setting free the dorsal portion with all the cerata. It then retired to the back of the tank, while the cerata—after separating, as they very readily do in Eolids—were left floating about in the water, untouched.

TANK A.—*Doris.*

(1) Tried and rejected by two shannies, then seized by the largest shanny and carried off to the back of the tank.

TANK B.—*Doris.*

(2) Several fish darted at the Nudibranch, but a large sole suddenly slipped up vertically between them and bolted it.

(3) Tried and rejected by six or eight plaice, and finally left on the sand.

(4, 5, 6) These three specimens were gently lowered into the tank by a net, so as to reach a shelf of the rock-work without attracting attention. They soon began to expand and move. One plaice swam up and looked or smelled at them, but did not touch them.

The action of the large sole in bolting *Doris* No. 2 above may possibly be explained as a result of the habit of competing for their food. Three or four other fish were darting at the Nudibranch, and the sole took the only possible course by which it could secure the prey—it made a rapid movement upwards between the snouts of its competitors and swallowed the *Doris* entire; there was evidently no time for examination.[1]

In the above experiments I have used altogether 53 Nudibranchs, offered to twelve different kinds of fish and other predaceous shore animals, and there have been over 130 distinct transactions between the fishes and the Nudibranchs. My general impression is that the order of edibility of the Nudibranchs offered to the fishes is: *Dendronotus, Doris, Ancula, Eolis; Eolis* being the most distasteful form, *Ancula* next, *Doris* less so, and *Dendronotus* edible, but, from its size, offering difficulties to the rather small fishes which we tried.

[1] The last number of the Journ. Mar. Biol. Assoc., containing Mr. Bateson's paper on the sense-organs and perceptions of fishes, only reached Liverpool after this article had been sent to NATURE. In regard to the sole being one of those fishes which hunt for their food and recognize it by the sense of smell alone, I would remark that the specimens in the aquarium here certainly seem to perceive their food as the plaice do by sight, the two kinds of fish often darting together at a food morsel—and, as I have just shown above, the sole being sometimes more alert than its competitors. Possibly these soles have changed their habits like the rockling described (p. 238) by Mr. Bateson.

The Nudibranchs were all healthy and good-sized specimens, and the fish were probably the right kind, being nearly all shore fishes found in the immediate neighbourhood of where the Nudibranchs live. Still, the conditions were, of course, to a certain extent artificial, and that must be taken into account in drawing conclusions. Dropping the Nudibranchs into the tank from above is unnatural, and may give rise to a misleading result, especially where the fish are accustomed to have their food thrown in from above, and *only receive edible food.* Then, again, at least some of the fish—those that have been some time in captivity—have been educated to compete with one another for the food. When *anything* is thrown in—a bit of white shell will do—there is at once a rush made upon the falling object, and no time is allowed for inspection or consideration. I would account for the seizing of *Eolis* by the shannies (very active, voracious, and apparently impulsive fishes), even when the prey is evidently distasteful and has brilliant warning colours, as a result of this acquired habit of competition, and of pouncing upon anything thrown into the tank. Still, there is a marked difference between the manner in which they take a cockle and say an *Ancula.* The cockle is taken right in and swallowed at once, while the distasteful Nudibranch, even if seized, is usually only partly taken into the mouth; in some cases, it is seen to be held by the very front of the jaws, and is then ejected with force.

Ancula has been a particularly interesting case. Start-with the general opinion that *Ancula* is a perfectly defenceless soft-bodied animal, I have been astonished to find that it is sometimes present on the rocks at Hilbre Island in great abundance, in very prominent and exposed situations, and that its colouring was not protective, but rendered it conspicuous. The experiments at the aquarium next showed me that this Nudibranch is distasteful to fishes and other shore animals, but for a time I did not understand why. Lately, however, Mr. Clubb and I have found[1] that, besides the abundant mucous glands scattered over the integument, *Ancula* possesses special large glands occupying the apices of the cerata, and opening to the exterior. These glands are placed just where an offensive organ would be most useful, and where the stinging cells are found in *Eolis*, and it seems probable enough that it is the presence of their secretion on the most outstanding parts of the body which renders the animal objectionable to fishes.

The protective colouring of *Doris bilamellata* may be accounted for in one or both of two ways: (*a*) it may serve to protect the animal from certain other shore animals which have not yet been experimented with, and to which the spicules and mucus of the *Doris* are not objectionable; and (*b*) it may save the animal from being tried by fishes, &c., not sufficiently aware of its (to them) distasteful nature.[2] It is obvious that, if an animal is not *thoroughly* objectionable, and has not yet become conspicuous with warning colours, it will be better for it to be protectively coloured. So we need not be surprised to find that some inconspicuous protectively coloured animals have certain offensive organs, and are distasteful to certain of their enemies. *Eolis* is a most distasteful form, and has conspicuous colours of a warning nature. *Ancula* is also distasteful, and is conspicuously coloured. *Doris* is less distasteful, and is still protectively coloured; while *Dendronotus*, which is, I believe, edible, is very effectually concealed, amongst the red seaweeds it lives on, by its large branched cerata and red-brown colours.

W. A. HERDMAN.

[1] See "Third Report on the Nudibranchiata of Liverpool Bay" (Trans. Biol. Soc. Liverpool, vol. iv.).

[2] What seems to be a very similar case has been pointed out by Mr. Garstang (Journ. Mar. Biol. Assoc., October 1889, p. 191), viz. the two British species of *Hermæa*, which are both protectively coloured, and have no stinging cells, and yet seem to possess the power of emitting, when irritated, an offensive fluid. I would expect to find that they were distasteful to at least some fishes.

THE PULKOVA REFRACTOR.

On the completion of the Pulkova Observatory, the jubilee of which has recently been celebrated, the late W. Struve published his "Description de l'Observatoire," which made the scientific world acquainted with the complete equipment of that institution. The additions which have been recently made to the Observatory, in order to preserve its high character and deserved reputation, have induced the authorities to publish what may be regarded as a supplement to that work, and the details now given of the history of the erection, and the results of a systematic examination, of the new refractor are not less interesting than were those of the old 15-inch.

The optical work of this recent addition, as is well known, is the work of Messrs. Alvan Clark, and the parallactic mounting that of Messrs. Repsold, and both of these eminent firms appear to have given, in their respective departments, complete satisfaction to the Russian authorities. Considerable difficulty was experienced in procuring the necessary disks for the object-glass, but eventually M. Feil, of Paris, supplied both flint and crown. The former appears to have given perfect satisfaction, but in the latter, near to the centre of the disk, there is collected, about a quarter of an inch below the surface, a quantity of small air-bubbles, which cover a space one and a half inch long by one-eighth broad. As in the opinion of the opticians, as well as of Prof. Pickering, this defect would not introduce any inconvenience, it was determined to proceed with the manufacture, rather than to wait for a more satisfactory casting. This defective spot, of elliptical shape, has no bad effect on the images of stars in the general use of the telescope, but bright objects, such as α Lyræ, are accompanied by two streams of false light, some minutes in length, in opposite directions, which appear to be produced by this defect in the crown lens. The position angle of these rays is found to be 114°-294°, and this direction is almost exactly perpendicular to the major axis of the air-bubble, which has been measured 23°-203°. Moreover, as this peculiarity is the more noticeable when the diameter of the object-glass is diminished by diaphragms, there can be no doubt that it is the result of diffraction produced by this spot.

The mounting of the object-glass in its cell differs in two respects from the plan generally adopted. The internal surfaces of the two lenses are separated by about six inches. Though this separation does not render the telescope available for photography, it doubtless tends to improve the achromatism; and, further, since openings are left in the cell for the purpose of cleaning the inner surfaces, currents of air can pass between the lenses and promote an equality of temperature between them and the atmosphere outside. The two lenses are not rigidly mounted in their cell of cast-iron, but, to prevent any risk of pinching or strain that might arise from the unequal expansion of metal and glass, a space of 0·5 mm is left. It was conjectured that a displacement of the lenses, relatively to each other, through this small amount would exercise no bad effect on the quality of the images, and this anticipation has been found correct.

The constants of the object-glass are as follows:—

	m.
Radii of the crown-glass lens ...	{ − 5·1054 { + 5·2831 (computed).
	mm.
Thickness of the crown	42·42
Thickness of the flint	26·06
	m.
Radii of the flint...	{ + 4·8386 { − 140·130

The focal lengths computed from these data, one of which, however, has been inferred, give the following results:—

				m.
Red,	λ = 636	...	Focal length	13·892
Yellow,	λ = 589	...	,, ,,	13·885
Green,	λ = 535	...	,, ,,	13·884
Blue,	λ = 481	...	,, ,,	13·892

from which it will be seen that the achromatism is satisfactory for the brighter parts of the visible spectrum, and in fact accords with that part of the spectrum which was originally selected for the minimum focal length, viz. λ = 0·00057.

The relative position at the focus for rays of different refrangibility was more accurately determined by the method of Prof. Vogel with the aid of a small spectroscope, as well as with the great spectroscope attached to the instrument. It was then seen that the part of the spectrum between D and b was so nearly linear that no certain determination of the difference of lengths for the different colours could be effected. For more distant parts of the spectrum the following measures were made of the distances of the three hydrogen lines from the normal position D − b:—

	mm.		
C	df = 3·0	...	$\frac{df}{f}$ = 0·00021
F	= 6·4	...	= 0·00045
Hγ	= 32·9	...	= 0·00233

It is not uninteresting to compare this result with that which Prof. Vogel obtained from measurements on the Vienna refractor of 26 inches, where the general character of the achromatism is very similar to that of the Pulkova refractor, since in both the red images are joined between D and F, and beyond F a rapid increase in the secondary spectrum is exhibited—a defect common to all objectives of silica glass.

In the Vienna object-glass the distances of the focus of the three rays before mentioned from the focal plane D − b are—

	mm.
C	2·7
F	6·0
Hγ	23·5

Consequently the diameters of the circle of chromatic aberration, reckoned on the same plane, are, for the two telescopes, as follows:—

Pulkova.				Vienna.			
	mm.				mm.		
Aperture	762			Aperture	675		
Focal length	14,120		"	Focal length	10,360		"
Diameter C	0·162	or	2·37	Diameter C	0·176	or	3·51
,, F	0·345	,,	5·05	,, F	0·391	,,	7·81
,, Hγ	1·775	,,	25·95	,, Hγ	1·831	,,	30·48

The advantages of a proportionately greater focal length in the case of the Pulkova instrument are shown by the somewhat smaller values of the angular diameter. This want of perfect achromatism makes itself felt in the Pulkova instrument in the images of stars remote from the optical axis. For a circle about 16′ in diameter, no appreciable effect is noticeable, but outside this radius the image has a tendency to exhibit a red fringe on the side turned towards the optical axis, and a violet on the side more remote.

The parallactic mounting appears to possess and retain a very satisfactory stability. In the case, however, of exceptionally heavy object-glasses, it is of interest to rigidly investigate the flexure of the tube. The total weight of the object-glass and cell is in this case 400 lbs. approximately, and considering the great distance from the centre of the instrument at which it is supported, the coefficient of flexure might be expected to be large. As a

matter of fact, this constant when derived from the observed zenith distances of known stars is 40″, but this amount, of course, refers only to the difference of flexure at the eye and object-glass ends. Direct measurements have, however, been made of the deflection of either end. For this purpose a small telescope was attached to the cradle of the instrument, with which a scale placed at either end could be read, the instrument being in both a vertical and horizontal position. The result was that the object-glass dropped 5·48 mm., and the eye end 3·22 mm.; when all necessary corrections have been made, this gives a flexure of 34″, a satisfactory agreement with that obtained from observations of stars. This deflection from the straight line was observed at eight different angles with reference to the horizon, and the results are fairly represented by supposing the flexure to vary simply as the sine of the zenith distance.

As regards the light-collecting capacity, it may be mentioned that the satellite of Neptune can be observed in an illuminated field without difficulty, and that the satellites of Mars were observed on fifteen evenings in 1886, a year in which the opposition fell very unfavourably for their observation. Hyperion is visible on a feebly illuminated red field, while Enceladus and Mimas are visible till quite close to the planet's disk. That there are difficulties in the employment of such large telescopes goes without saying: it is, however, satisfactory to notice that the number of evenings on which the telescope cannot be used from bad definition or adverse meteorological conditions is not larger than in the case of the 15-inch equatorial. W. E. P.

SIR WARINGTON W. SMYTH, F.R.S.

MINING has suffered an irreparable loss by the death of Sir Warington Smyth, which occurred suddenly at his house in Inverness Terrace on the 19th inst. He was the eldest son of Admiral W. H. Smyth, F.R.S., and was born at Naples 73 years ago. He was educated at Westminster and Bedford Schools and at Trinity College, Cambridge, where he exhibited great skill as an oarsman, being one of the winning University crew on the Thames in 1839. In that year he graduated, and obtained a travelling fellowship which enabled him to devote more than four years to a journey through the chief mining districts of Europe, and thus to lay the foundation of that practical knowledge which subsequently made him the greatest British authority on mining matters. Continental travelling in 1839 was by no means the easy matter it is now, and his journey through the Harz, Saxony, Austria, Hungary, Turkey, and Asia Minor, was not devoid of risk and adventure. As a result of his travels through the European and Asiatic dominions of the Sultan, he published in 1854 a work entitled "A Year with the Turks." In subsequent years, he visited during his vacations the more important mines of France, Belgium, Spain, Italy, and Norway. His official career began in 1844, when he was appointed by Sir Henry De la Beche to a post on the Geological Survey, and while holding this position he explored and geologically mapped the metalliferous districts of Devon and Cornwall, North Wales, and Ireland, and the coal-fields of Lancashire and Yorkshire, North Staffordshire and Derbyshire. In 1845 he joined the Geological Society, and in 1866 was elected President of that body. For the last 17 years he has acted as foreign secretary, in which post his rare linguistic powers proved of great service to the Society. On the foundation of the Royal School of Mines in 1851, he was appointed the first lecturer on mining and mineralogy. On the reorganization of the School in 1881, he gave up the Chair of Mineralogy, but acted as Professor of Mining until his death. He held the office of inspector of the mines in the Duchy of Cornwall, and in 1857 he was also appointed comptroller of all the mineral properties belonging to the Crown. It would be tedious to enumerate the long list of Royal Commissions and International Exhibitions with which Sir Warington was prominently associated. His report as Secretary of the Jury on the mining industry at the Exhibition of 1862 is a model of what such a work should be, and to his energy on the Council of the Inventions Exhibition of 1885 the success of the mining section was largely due.

In 1879 a Royal Commission was appointed to inquire into accidents in mines and the possible means of preventing their occurrence and of limiting their disastrous consequences. Mr. Smyth was appointed Chairman, and, in order to secure time to attend to the duties of this arduous and honorary office, he resigned the post of Examiner to the Science and Art Department—an office he had held for several years. The Commission ended its work in 1886, and during the seven years it was in existence some thousands of experiments were made, and the Report, covering 858 pages, definitely settled many important questions bearing upon the diminution of accidents in mines.

To his scientific attainments, Sir Warington added singular literary skill. His early classical training enabled him to write with an elegance and vigour unfortunately rare in technical works. He spared no pains, and neglected no details. As a teacher he was very popular with his pupils, his success as a lecturer being due not only to his finished delivery, but also to his skill as a draughtsman, which enabled him to dispense with the aid of elaborate diagrams, and to rely merely on accurate blackboard sketches, which he drew with great rapidity in the presence of his class. His reputation as Professor attracted to the School of Mines students from all parts of the world, and no better evidence of the excellence of his teaching could be adduced than that afforded by the important positions so many of his pupils occupy in the mining world. Of his literary works, the most important is his "Rudimentary Treatise on Coal-Mining"—a standard work, bearing internal evidence of not being mere extracts of books, written in 1867, and now in its seventh edition. Besides this, he wrote the articles on mining for "Ure's Dictionary" and for Stanford's series of "British Manufacturing Industries," 1876.

For his labours on the Accidents in Mines Commission, and for his other public services, he received the somewhat tardy acknowledgment of knighthood on the occasion of Her Majesty's Jubilee. Throughout his life he refused the great pecuniary rewards offered by the commercial branches of mining, and preferred to devote the half-century during which he was engaged in business connected with mines to the service of science and of the State. Although he had been in ill-health for some time, he never neglected his official duties. He died in harness, with a partially corrected examination paper on the table before him. He was buried yesterday at St. Erth, in Cornwall, not far from his home at Marazion, in the centre of the mining district with which he was so long associated. B. H. B.

NOTES.

WITH the consent of the Prince of Wales, the President, the Council of the Society of Arts has awarded the Albert Medal to Dr. W. H. Perkin, F.R.S., "for his discovery of the method of obtaining colouring matter from coal tar, a discovery which led to the establishment of a new and important industry, and to the utilization of large quantities of a previously worthless material."

THE Essex Field Club and the subscribers to the Gilbert Club will hold a meeting at Colchester on Saturday, July 5, in memory of William Gilbert, the founder of the science of

electricity, who was born and died at Colchester. A visit will be made to Gilbert's house and tomb, and Prof. Silvanus P. Thompson will lecture on "The Early Magnetic Experiments of Gilbert of Colchester." The chair at the public luncheon will be taken by Lord Rayleigh, F.R.S., Vice-President of the Essex Field Club and the Gilbert Club. Any persons wishing to attend the meeting may obtain full particulars on application to Mr. W. Cole, Hon. Sec., Buckhurst Hill, Essex.

THERE is no foundation for the report that Dr. G. J. Romanes is a candidate for the Linacre Professorship of Human and Comparative Anatomy, Oxford.

THE Photographic Convention of the United Kingdom is now holding its annual meetings at Chester. The series of meetings was opened on Monday, and will not be concluded until Saturday. At the official welcome of the Convention by the mayor, on Monday, Mr. A. Pringle, the retiring President, introduced his successor, Mr. C. H. Bothamley. In the course of his address, the new President said that the events of last year contained nothing of first-rate importance in photography; no discoveries of far-reaching influence had disturbed the photographic world. But a good deal of interest had been excited by the announcement that advances had been made towards the solution of the problem of photographing objects in their natural colours. Coloured photographs, more or less imperfect, had been made several times, but whether they should ever get a chromatic negative process was at present entirely a matter of conjecture, and so far even the direction in which the solution was to be looked for was not apparent. Photo-mechanical printing had not presented any new feature during the past year, but the processes already in operation had been taken much greater advantage of. The applications of photography to science were becoming every day more and more numerous, and he did not hesitate to say that it was here that photography had won, and probably would win in the future, its greatest triumph.

THE Elizabeth Thompson Science Fund, which has been established by Mrs. Elizabeth Thompson, of Stamford, Conn., "for the advancement and prosecution of scientific research in its broadest sense," now amounts to 26,000 dollars. As accumulated income will be available in December next, the trustees desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but *Science* says it is the intention of the trustees to give the preference to those investigations which cannot otherwise be provided for, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from the fund, in order to receive consideration, must be accompanied by full information, especially in regard to the following points: (1) precise amount required; (2) exact nature of the investigation proposed; (3) conditions under which the research is to be prosecuted; (4) manner in which the appropriation asked for is to be expended. All applications should reach, before December 1890, the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. It is intended that new grants shall be made at the end of 1890. The trustees are disinclined for the present to make any grant exceeding 300 dollars: decided preference will be given to applications for smaller amounts.

THE U.S. National Academy of Sciences is considering whether it might not be expedient to divide its membership into classes. The following classification has been proposed: mathematics, physics, astronomy, geodesy and mechanics, chemistry, geology, botany, zoology, anthropology, and political economy and statistics. The *American Naturalist*, commenting on this list, suggests that a special place should be reserved for psychology. It also expresses a hope that the division into classes will not be made a pretext for increasing the membership to above one hundred persons.

LAST week Mr. Mundella asked the Vice-President of the Council of Education whether he had received remonstrances from the principal educational authorities and managers of higher elementary schools in England and Scotland against Article 40 of the Science and Art Department, which excluded scholars in public elementary schools from being henceforward examined or earning grants in science; whether he had seen the statement of the National Association for the Promotion of Technical Education, which described this circular "as one of the most serious blows which had been struck for some years at the development of scientific and technical education"; and whether, having regard to the feeling with which the circular had been received, he would cause it to be withdrawn. Sir W. Hart Dyke replied that the matter was under consideration; and he has since issued an official letter, stating that the Department had anticipated the objection which had been made, and had decided to substitute a provision which would not in any way interfere with the present system of science instruction so admirably carried out by many School Boards. With reference to a complaint that in another circular dealing with the question of manual instruction in public elementary schools, a proviso had been inserted requiring such instruction to be given out of school hours, Sir W. Hart Dyke states that a supplementary circular will be shortly issued in order to remove the doubts which exist on the subject. Sir William believes there will be no difficulty in continuing the plan now adopted, providing the time devoted to manual instruction by any scholar for the purposes of the grant is outside the minimum period required to constitute an attendance under Article 12 of the Code, which does not prevent any further time from being given to the subject within the ordinary school hours.

THE *Kew Bulletin* publishes every year a complete list of the garden plants annually described in botanical and horticultural publications, both English and foreign. In Appendix II., which has just been issued, there is a list of all the introductions recorded during 1889. It is pointed out that these lists are indispensable to the maintenance of a correct nomenclature, especially in the smaller botanical establishments in correspondence with Kew, which are, as a rule, only scantily provided with horticultural periodicals. Such a list will also afford information respecting new plants under cultivation at the Kew establishment, many of which will be distributed from it in the regular course of exchange with other botanic gardens.

THE *Botanical Gazette* informs us that the first Annual Report of the Director of the Missouri Botanic Garden has been issued. It contains a statement of the changes that are being made in the Gardens, or that are in immediate prospect; and a map of the grounds on a large scale is being prepared. The Director requests from authors copies of their publications for the library, from collectors specimens for the herbarium, and promises all feasible assistance in work calculated to promote botanical knowledge.

THE first number is published of a new quarterly journal, *Le Diatomiste*, specially devoted to the natural history and literature of diatoms. It is published at 168 Rue Saint-Antoine, Paris, under the editorship of M. J. Tempère, assisted by MM. Brun, Bergon, Cleve, Dutertre, Grove, and Peragallo. The present number (quarto, with two plates) contains descriptions of a number of new species, and a bibliography of recent diatomological literature.

IN the *Journal of the Straits Branch of the Royal Asiatic Society*, Mr. Alfred Everett has just published a most important list of the birds of the Bornean group of islands. Hitherto the work of Salvadori has been the standard record for Bornean ornithology, but the numerous discoveries of recent years have rendered that author's "Uccelli di Borneo" considerably out of date, and the Catalogue of Bornean birds published by Dr. Vorderman in 1886 is a list of names merely. The work just completed by Mr. Everett will therefore be of great assistance to ornithologists, as it gives references to all the recent scientific memoirs on Borneo, published in England and in Germany. 570 species have now been recorded from the islands, the numbers having been considerably increased by the recent discoveries of the author himself and Mr. John Whitehead's expedition to Kina Balu. Mr. Everett has given a carefully compiled list of the localities where the species have been found by himself and other travellers. Two very good maps of Borneo are given, one "showing roughly the distribution of highlands and lowlands," with all the best-known collecting stations indicated as well; and the other being a map of Palawan, showing by the soundings that this island is intrinsically a part of Borneo rather than of the Philippine archipelago.

IN the current number of the *Board of Trade Journal*, it is stated that the French Consul-General at Warsaw has informed his Government of the establishment of a commercial museum in Warsaw. This is to form a permanent exhibition of specimens of the products and manufactures of Poland, as well as a bureau of information for Russian or foreign merchants. At a small charge all persons can be supplied at the office of this museum with information on any subject connected with trade. The museum is at present at No. 66 Faubourg de Cracovie, Warsaw.

A METEOROLOGICAL SOCIETY is to be established in New York, where many persons are giving attention to weather science, owing to the relations existing between some branch thereof and their own vocation. It is intended that the Society shall be purely local at first.

Das Wetter for May contains an article by Dr. P. Perlewitz upon the influence of the town of Berlin upon its climate. He finds that the difference of the mean temperature between the town and the open country outside differs, in various months, from 0°·7 to 2°·3, the town being always warmer. The smallest differences are in spring and winter. The greatest daily differences are found to be in the evening, owing to a retardation of radiation in the town; from this time the difference decreases until about midday, when there is no perceptible difference between the two localities. Dr. Hann has found similar results for Vienna, but the differences there are smaller, owing to the better exposure of the town station. The humidity is less in the town than in the country; in the evening, in June and July, the difference amounts to above 19 per cent. No appreciable effect appears to be exerted by the town upon the rainfall, as compared with that of the country stations.

DR. G. HELLMANN, to whom meteorologists are indebted for various interesting investigations into the history of that science, has contributed to *Himmel und Erde* (Heft. 3 and 4, 1890) two instructive articles on "the beginnings of meteorological observations and instruments." He divides the history of the development of observations into three periods: (1) that ending with the middle of the fifteenth century, up to which time they were of a very fragmentary and almost aimless character; (2) that in which observations were taken, at least once a day; and (3) that in which they were systematically taken with instruments, dating from about the middle of the seventeenth century. It is not exactly known who first kept a regular meteorological journal, but Humboldt attributes it to Columbus, on his first voyage to America in 1492, while the Italians also appear to have made daily observations from the middle of the fifteenth century. The wind-vane is by far the oldest of the meteorological instruments. In the periods of Homer and Hesiod, in the ninth and eighth centuries B.C., the qualities of the winds were correctly described. The first arrangement for observing the wind-direction is the Temple of Winds at Athens, which was built about 100 years B.C. A picture of this tower is given by Dr. Hellmann. Eginhard, in the reign of Charlemagne, denoted the winds by the four cardinal points, and their variations. The first instrument for denoting the *force* of the wind is ascribed to Robert Hooke (1667); this instrument is essentially the same as that now used and known as Wild's pendulum anemometer. The absorption or organic hygrometer was invented about the middle of the fifteenth century, by N. de Cusa, although the invention is generally ascribed to L. da Vinci. The first condensation hygrometer is attributed to the Grand Duke Ferdinand II. of Tuscany. The first continuous hygrometrical observations appear to have been by R. Boyle, at Oxford, in June 1666. The first thermometer is attributed to G. Galilei, towards the end of the sixteenth century. Some few years later, the instrument was improved, although the freezing-point was the only fixed point determined, and the graduation was made by means of little knobs in the glass, every tenth one being enamelled. The first rain-gauge was used by B. Castelli in 1639, although usually a later date is quoted. The discovery of the Torricellian tube, in 1643, is too well known to require special remark. These are only a few of the very interesting points referred to in Dr. Hellmann's instructive investigations.

IN an interesting paper contributed to the May number of the Ottawa *Naturalist*, and now reprinted separately, Dr. G. M. Dawson brings together some striking facts with regard to the extent of Canadian territory which is still unexplored. The entire area of the Dominion is computed at 3,470,257 square miles, and he calculates that an area of 954,000 square miles of the continent alone, exclusive of the inhospitable detached Arctic portions, is for all practical purposes entirely unknown. In this estimate the area of the unexplored country is reduced to a minimum by the mode of definition employed, and Dr. Dawson thinks we may safely assume that it is about one million square miles, or between one-third and one-fourth of the whole. That the aggregate of unknown territory is so vast is not quite creditable to Canadian energy; but Dr. Dawson hopes that the task of exploration will be undertaken by no one who has not the necessary scientific qualifications. "The explorer or surveyor," he says, "must possess some knowledge of geology and botany, as well as such scientific training as may enable him to make intelligent and accurate observations of any natural features or phenomena with which he may come in contact."

THERE is a disease in Japan known as *kakké*, a disorder of the kidneys communicated by bacilli, and closely related to the more virulent *beri-beri*. From the distribution of *kakké*, M. Gueit has recently drawn conclusions as to the ethnic composition of the present population of Japan. The fact that Chinese always escape the disease, even in localities where it is very prevalent, indicates (in his opinion) that the Chinese or Mongolian element is not the dominant one. He finds three constituents in the population: (1) descendants of Ainos; (2) of Negritos; and (3) a Malayan element, which is the most prominent. Wherever the Malayan goes, he brings with him the *beri-beri* order of disease his liability to this being probably due to the Hindu blood in him. From India we find *beri-beri* spread, like the Malays, to Madagascar on the one side, and to Japan on the other; we meet with it also in Java, Sumatra, &c. According to the proportion of Malay blood in the natives of Japan is the frequency of the malady, which occurs in various forms and under different names. As to the Negrito element in Japan, M. Gueit

found an interesting proof of it in the island of Sikok, in the form of a small statuette of Buddha, having the characteristic nose and hair of the Negritos.

IT is a well-known fact in biology that bacteria and bacilli absorb anilin and are killed by it. Two German observers—Stilling and Wortmann—have recently considered the possibility of utilizing this property in medical treatment (*Humboldt*). The diffusibility and harmlessness of violet anilin dyes (called, for brevity, "methyl-violet") without arsenic, in small doses, were first demonstrated on rabbits and guinea-pigs. Then certain eye-disorders were produced in those animals, and treated with anilin solution, the results being excellent. The authors proceeded to operate on the human subject. A skin-ulcer on a scrofulous child, which had been treated for a month with the ordinary antiseptic agents without success, was gradually healed by daily dropping a little anilin solution on the sore; and similar good results were had with bad cases of eye-disease. It soon appeared that many surgical cases were open to successful treatment in this way; and that, in general, wounds and sores developing suppuration could be sterilized with anilin. It is also thought that cases of internal inflammation, as in pleuritis and peritonitis, may prove to be not beyond the reach of this order of treatment.

MESSRS. FRIEDLÄNDER AND SON, Berlin, have issued an important monograph, by Dr. Max Blanckenhorn, on the development of the Cretaceous system in Central and Northern Syria. The author devotes especial attention to palæontological phenomena.

A MONOGRAPH, by Dr. L. Tausch von Gloeckelsthurn, on the fauna of the "gray chalk" of the Southern Alps, has been issued by A. Hölder, Vienna. The work is illustrated with nine lithographic plates.

IN the Statistical Report of the Colony of Victoria, just issued, the following are given as the latitudes and longitudes of the capitals of the Australian colonies, corrected by Mr. Ellery, the Government Astronomer of Victoria:—

Colony.	Capital City.	Latitude S.	Longitude E.
		° ′ ″	° ′ ″
Victoria	Melbourne ...	37 49 53	144 58 32
New South Wales ...	Sydney ...	33 51 41	151 12 23
Queensland	Brisbane ...	27 28 0	153 1 36
South Australia ...	Adelaide ...	34 55 34	138 35 4
Western Australia ...	Perth	31 57 24	115 52 42
Tasmania	Hobart ...	42 53 25	147 19 57
New Zealand	Wellington ...	41 16 25	174 46 38

WE are glad to learn that after eight years' cessation, Mr. John Fryer, of Shanghai, has revived his Chinese periodical, the title of which is best translated *Science Quarterly*. The first number of the re-issue contains 128 pages of reading matter of great variety. From a review in the *North China Herald*, by Dr. Martin, of Pekin, we gather that the science articles open with a chapter on appliances for illustrating the principles of mechanics. This paper forms a connecting link with the last number of the series, taking up the subject where it was dropped, and promising to carry it on to completion. The second paper begins a treatise on the principles of mechanical drawing, a subject in which the Chinese are beginning to take much interest. This is followed by the great topic of the day—railways. The steps necessary for the initiation and conduct of a railway enterprise are pointed out, the question of gauge is discussed, and statistics of cost are supplied. Then comes an elaborate paper on the state of the silk trade in China, pointing out the way to improvement, and stimulating the Chinese by the example of Japan and Italy. There is a paper on the sanitary conditions to be observed in the construction of dwellings, and one on medicinal plants, one on several strange vegetable productions, and one on entomology. Besides these, there are short papers on Edison's phonograph, the Eiffel tower, and on observatories and telescopes. The dessert which closes the feast is a profound disquisition by Dr. Edkins on the evolution of the Chinese language. It will no doubt surprise the natives to find that a foreigner has something to teach them in respect to their own language, both written and spoken. At the end are mathematical problems, in the estimation of native scholars the first essential of a scientific magazine. Nearly all the papers are profusely illustrated.

THE additions to the Zoological Society's Gardens during the past week include two Lions (*Felis leo*, juv. ♂ ♀) from Kattywar, India, presented by H.R.H. the Duke of Clarence and Avondale; a Grey Ichneumon (*Herpestes griseus* ♂) from India, presented by Mrs. H. F. Pollock; a Common Badger (*Meles taxus*), British, presented by Mr. W. H. B. Pain; a —— Galago (*Galago* sp. inc.) from South Africa, presented by Mr. Walter Carlile; a Spur-winged Goose (*Plectropterus gambensis*) from West Africa, presented by Mrs. Quayle Jones; two Common Rheas (*Rhea americana*) from South America, presented Mr. A. W. Neeld; three Grey Sparrows (*Passer simplex*) from West Africa, a Tintillon Chaffinch (*Fringilla tintillon*), two Yellow-throated Rock Sparrows (*Petronia petronella*) from Teneriffe, a Rosy Bullfinch (*Erythrospiza githaginea*) from the Canary Islands, presented by Mr. Edmund G. Meade-Waldo; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Mr. F. C. S. Roper, F.Z.S.; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mrs. Obbard; two Common Barn Owls (*Strix flammea*), British, presented respectively by Mr. Charles Faulkner and Mrs. Frederick Tibbs; an American Box Tortoise (*Terrapene carinata*), a Horned Lizard (*Phrynosoma cornutum*) from Mexico, presented by Mr. John Pettit; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. C. S. Morris; four Houbara Bustards (*Houbara undulata* 2 ♂ 2 ♀) from the Canary Islands, a Bonnet Monkey (*Macacus sinicus* ♂) from India, deposited; six Speigel Carp (*Cyprinus carpio*, var.), European Fresh Waters, purchased; two Bennett's Wallabys (*Halmaturus bennetti* ♀ ♀), a Derbian Wallaby (*Halmaturus derbianus* ♀), two Four-horned Antelopes (*Tetraceros quadricornis* ♀ ♀), a Burrhel Wild Sheep (*Ovis burrhel* ♀), a Thar (*Capra jemlaica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on June 26 = 16h. 19m. 54s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4230	—	—	16 37 45	+36 41
(1) β Lyræ	Var.	—	18 46 0	+33 14
(3) α Scorpii	1	Redddish-yellow.	16 22 40	+26 14
(4) β Herculis	2	Yellow.	16 25 30	+21 44
(5) δ Herculis	3	Bluish-white.	17 10 30	+24 58
(6) S Leonis	Var.	Yellowish.	11 5 9	+ 6 3·5

Remarks.

(1) This is the bright cluster of stars in Hercules which is probably well known to every possessor of a telescope. Seeing that it certainly consists of separate and distinct stars, no nebulosity being shown in Mr. Roberts's photograph of it, Dr. Huggins's observation of its spectrum in 1866 is very remarkable. He says:—"Spectrum of the central blaze continuous.

Spectrum ends abruptly in the orange. The light of the brighter part is not uniform; probably it is crossed either by bright lines or by lines of absorption" (Phil. Trans. 1866). As yet we know nothing of the spectra of the components of any star cluster except in the case of the loose cluster of the Pleiades, and in that case we know that the spectra are all of the same type—namely, Group IV. It seems pretty evident that the stars of the cluster in Hercules cannot have spectra of this kind; otherwise, their integrated light would not end abruptly in the orange, and the irregularities would only be obvious in the blue end, where the thick hydrogen lines ought to be visible. The absence of red light would lead rather to the supposition of bright lines than dark ones. Further investigations, with considerable optical power, may therefore lead to interesting results. It may be noted that Vogel, in 1872, recorded simply a continuous spectrum, but his attention had probably not been directed to Dr. Huggins's statement.

(2) The question of the periodicity of the appearance of the bright lines in β Lyræ cannot yet be said to have been satisfactorily settled, and as the star will be visible for some months, further continuous observations are desirable. It is not necessary here to recapitulate all the observations which lead to the conclusion that there is a periodicity in the spectrum. Gothard has probably given more attention to the star than any other observer, and he succeeded in following the variations of the line D_3 through several periods "from a bright, almost dazzling light to complete disappearance. . . . The variation is most marked in the case of D_3; it is much less striking in the hydrogen lines, although they, and probably also the dark bands in the red, are subject to a periodical variation." The period has been provisionally estimated as 7 days, but it does not seem to depend upon the fluctuations in the brightness of the star. In my own observations I have found that the bright lines in this star are best seen when no cylindrical lens is employed, and this has also been noted by other observers. Further observations, to be of any value, should be made as frequently as possible, and over a long period.

(3) Dunér describes the spectrum of this star as one of the most magnificent of Group II., the bands 1–9 being wide and dark. He also states that there is a narrow band between bands 3 and 4. As the spectrum is a bright one, this is a good opportunity for comparing the dark flutings with the brightest flutings of manganese, lead, and magnesium. In the recently issued volume of spectroscopic observations at Greenwich, Mr. Maunder states that he has found the bright green band in α Herculis coincident with the brightest carbon fluting and possessing the same characteristics. A similar comparison should also be made with α Scorpii.

(4 and 5) These stars, according to the observations of Gothard and others, have spectra of the solar type and of Group IV. respectively. The usual more detailed observations are required in each case.

(6) The spectrum of this variable has not yet been recorded. The magnitude ranges from about 9 to <13 in a period of about 188 days. There will be a maximum about July 2.

A. FOWLER.

GREENWICH SPECTROSCOPIC RESULTS.—These results for 1888 contain observations of γ Cassiopeiæ, Mira Ceti, α Orionis, α Herculis, β Lyræ, R Cygni, P Cygni, β Pegasi, and Comets a and e 1888. On October 5, 1888, ten measures were made of a bright line in the violet part of the spectrum of Mira Ceti; the mean wave-length found was 4343·37, indicating that it was the third line of hydrogen. F and D_3 were searched for on this occasion, but without success. The spectrum of α Herculis was compared with those of carbon and manganese, as given by a Bunsen flame on several occasions, and it is noted: "The green band of the carbon spectrum accorded, both as to position and appearance, with the bright interspace or 'zone' to the blue of Band VII. (Dunér's numeration). So far as the dispersion employed would show, no accordance could be more complete, both as to the position of the edge and the gradation of the fading." The blue carbon band was also found to present an approximation in position and appearance to a bright zone in the blue. The wave-length of the brightest bands in the manganese spectrum was determined as 5579, and that of the more refrangible edge of Dunér's Band IV. as 5592, whence it is concluded that the connection of the spectrum of the star with the manganese spectrum did not appear to be made out. A bright line at 5873·92, that is, D_3, was measured in β Lyræ on August 10, 1888, was seen less distinctly a month later, and was found again to be quite distinct on September 19; two days later, D_3 was seen very bright, and C and F were also visible. D_3 was visible, but faint, on October 1; F could not be seen, and C was only suspected. On October 19, C and F were not visible as bright lines, but were first suspected as dark lines, whilst D_3 was glimpsed occasionally as a feeble bright line. R Cygni was observed on September 21, D_3 was identified with probability in its spectrum, and F with certainty; and, on October 1, ten measures were made of the F line in P Cygni. Comet a 1888 was observed on April 19, 1888; its spectrum appeared mainly continuous; two bright bands were just glimpsed, coincident with the bands in the green and yellow of the spectrum of a Bunsen flame, the band in the blue being suspected. On May 3 the spectrum was practically wholly continuous, traces of the green band only being suspected. Comet e 1888, observed on November 27, showed a local ill-defined brightening, corresponding nearly to the great carbon band, but apparently further towards the blue, otherwise it was perfectly continuous.

THE ROTATION OF VENUS.—Signor Schiaparelli has recently made an extended inquiry into the question of the rotation of the planet Venus, and has brought many facts to light concerning it (*Rendiconti del R. Istituto Lombardo*, vol. xxiii.). He finds, from observations of very definite spots, that the time of rotation of the planet is 224·7 days—that is to say, Venus, like the moon, and probably Mercury, rotates on her axis in the same time that she takes to make a sidereal revolution around the sun; the axis of rotation being nearly perpendicular to the plane of the orbit. By investigating the writings of previous astronomers who have estimated the rotation period, Signor Schiaparelli concludes that those observations which have been supposed to fix the time as about 24 hours are open to question. Domenico Cassini's observations of bright markings in 1866–67 are shown to have been wrongly interpreted, a discussion of them indicating that they also support a period of rotation of 224·7 days.

GEOGRAPHICAL NOTES.

THE Russian Geographical Society has received fresh news from M. Grombchevsky as to his attempts to penetrate into Tibet from the north. In the autumn of 1889 the expedition explored the Uprang, a tributary of the Raskem-daria, tried to enter again into Kanjut, and, having failed to do so, explored the tributaries of the Raskem river which flow from the Himalayas. On November 21, M. Grombchevsky, accompanied by two men only, crossed the Kara-korum Pass, and went to the Pahnu mountaineers, who live by sheep-breeding, and suffer a good deal from the Kanjut robbers. On December 7 the expedition was at the small fort of Shahi-dulla-hodja; the winter had come, and the thermometer fell in the nights to − 20° Celsius. Nevertheless, M. Grombchevsky, with two men only and a guide, explored the passes leading to Kara-korum across the Raskem ridge. The tent had to be abandoned, although the temperature was − 35°, and the party was soon obliged to return. On January 7, after having followed for some distance the Kara-kash river, the small party began its ascent of the steep slopes of the Tibet border-ridge. The plateau itself proved to be a desert, 17,000 feet high, upon which a few yaks, *Kulangs*, and mountain sheep were grazing. A very high ridge, called by M. Grombchevsky the Yurung-kash ridge, was crossed, the pass receiving the name of "Russian." But the horses of the expedition were quite attenuated, and on January 13 the party was brought into a perilous condition by a frightful snow-storm and a temperature of − 27°, without having either a tent or any kind of fuel. M. Grombchevsky was compelled to return, marching all day long. After having made another unsuccessful attempt at crossing the Hindu-tash Pass, the expedition went to Kilian, and thence to Polu, thus connecting its surveys with those of Prjevalsky. A telegram received from New Marghelan, in Russian Turkestan, announces that the explorer and his men have returned safely, and are making new schemes for further exploration. A map, annexed to the last issue of the *Isvestia* of the Russian Geographical Society, embodies the surveys made by M. Grombchevsky in 1888 and M. Grum-Grzimailo in 1887.

IN the course of last year the Geographical Society of Berlin published no fewer than thirty-nine remarkable maps. Three of them are reproduced from those of Mercator, now in the

town library of Breslau. Two others—a map of Europe (finished in 1554) and one of England (of 1564)—are unique. Another is the large map of the world, of which there are only two copies in existence, the second one being at the Paris National Library. The Society has agreed to publish the details of Dr. Konrad Kretschmar's journey to Rome, undertaken in the Middle Ages for purposes of research.

THE LADIES' CONVERSAZIONE OF THE ROYAL SOCIETY.

THE Ladies' *Conversazione* of the Royal Society was held on June 18, and was, as usual, a great success. Many of the exhibits were the same as those shown at the *conversazione* on May 14. Among those which had not been previously shown were the following:—

Exhibited by the Director-General of Ordnance Factories:—Magazine rifle, Mark I. The new magazine rifle now being made for the British Army. It has a calibre of 0"·303, is on the bolt principle, and is provided with a detachable magazine underneath, to hold eight cartridges; a cut-off on the right side enables it to be used as a single loader. It has two sets of sights, the ordinary ones are graduated up to 1900 yards, the long-range sights on the left side up to 3500 yards. The sword-bayonet, which is attached underneath the barrel, has a double-edged blade 12" long.

Exhibited by the Director-General of the Geological Survey:—Diagrams illustrating some of the most ancient topography of the British Isles. (*a*) Corry on Ben More, Assynt. The rough bossy ground in the middle is the Archæan gneiss, the most ancient rock in this country. Above it to the left comes the Torridon sandstone, forming a range of cliffs, and lying unconformably on the gneiss. At the summit of the Corry, on the crest of the ridge, lies the early Palæozoic quartzite, which steals across the sandstone until it rests directly on the gneiss. (*b*) Sleagach, Loch Maree. The pinkish bossy rock is the old gneiss, which rises into a group of hills that have been buried under the Torridon sandstone. By prolonged and enormous denudation of the overlying sandstone, the gneiss hills have been uncovered, and now reveal a portion of the oldest known topography of Britain. The gneiss hill to the right rises to a height of 2500 feet, and in ascending it one can walk along the ancient shore-line and traverse beach after beach that was piled up over the sinking land. (*c*) View from the south shoulder of Sleagach looking east. The bossy hills of gneiss rise towards the left hand to a height of 3000 feet above the sea. The overlying cover of Torridon sandstone, though enormously denuded, still forms a range of lofty hills, beneath which knobs of gneiss at different elevations may be seen protruding. The quartzite (coloured yellow) caps the mountains to the right until a mass of the old gneiss overlies it. This cake of the most ancient rock of the region has been torn up and thrust over the younger formation. The line of junction or "thrust-plane" between them descends into the plain, and runs for miles to the westward. (*d*) Meall a Ghubhais, Loch Maree. The upper part of the mountain is a cake of Torridon sandstone, which has been driven westward by the same gigantic terrestrial movements just referred to, and has been placed upon the quartzite group of rocks which ought really to lie above it. In the lower part of the diagram the sandstone is seen in its normal position below the quartzite. (*e*) Section of Meall a Ghubhais, to show the detailed geological structure of the mountain. It will be observed that the upper shifted mass of Torridon sandstone is traversed by several thrust-planes, and that portions of the old gneiss have likewise been driven westward underneath it.

Exhibited by Mrs. F. W. H. Myers:—(1) Platinotype photographs. (2) Photographs on fabrics.

Exhibited by Sir William Bowman, Bart., F.R.S.:—(1) Jubilee portrait of the late Prof. Donders, For. Mem. R.S., painted by Mrs. Donders (Hubrecht). Gold Medal awarded at the Exposition International, Munich, 1888. Ultimately destined for the National Museum, Amsterdam. (2) Uncompleted portrait of the same, 1873, by G. F. Watts, R.A.

Exhibited by Prof. W. C. Roberts-Austen, C.B., F.R.S. Measurement of high temperatures. Experimental determination of the melting-point of gold (1045° C.) and of silver (945° C.), by means of Le Chatelier's pyrometer. This consists of a thermo-couple, composed of wires of platinum and platinum alloyed with 10 per cent. of rhodium, connected with a dead-beat galvanometer. The pyrometer scale has been calibrated by heating the thermo-couple to certain known temperatures determined by the air thermometer.

Exhibited by Prof. A. M. Worthington:—An apparatus for stretching a liquid and measuring simultaneously the stress and strain.

Exhibited by Mr. P. L. Sclater, F.R.S.:—Portrait of Dr. Emin Pasha, C.M.Z.S., and original letter from him, addressed to Mr. Sclater, dated Wadelai, April 15th, 1887.

Exhibited by the Postmaster-General:—Hughes's type-printing telegraphs, working to the Continent. This apparatus is mainly mechanical, the electrical action being confined to the sending a single short pulsation of current at the instant the type-wheel is in the proper position, and only one wave of current is needed to produce a letter. The sending and receiving instruments are combined. The key-board consists of as many keys as there are letters and signs to be printed. Connecting with the keys and corresponding with them, and also with the type-wheel, is a set of pins arranged radially in a circular horizontal plate. An arm revolves over these pins without touching them until a key is depressed, when a current is sent into the line. The instruments are caused to run approximately isochronously by means of suitable adjustments, and they are afterwards maintained in synchronism automatically by the actual working. The instrument is eminently suitable for Continental message traffic, for which purpose it is largely used. The three working instruments shown were connected with Paris, Berlin, and Rome. In the course of the evening the President held communication with Profs. Helmholtz and Du Bois-Reymond in Berlin, Prof. Mascart in Paris, and Prof. Cannizzaro in Rome.

Exhibited by Mr. Walter Gardiner, F.R.S.:—(1) Specimens of aquatic fen plants and algæ occurring in the neighbourhood of Cambridge. (2) Specimens illustrating the exhibitor's paper on a new method of printing photographic negatives, employing living leaves in place of sensitive paper.

Exhibited by Dr. Pole, F.R.S.:—Diagrams in illustration of colour-blindness.

Exhibited by Dr. Karl Grossmann:—Tests for colour-blindness.

Exhibited by Prof. J. W. Judd, F.R.S.:—Specimens of a remarkable nickel-iron alloy (awaruite), of terrestrial origin, from New Zealand, and of the minerals and rocks with which it is associated. Sent by Prof. G. H. F. Ulrich, of the Dunedin University, N.Z. This curious mineral, consisting of 2Ni + Fe, was analyzed and named by Mr. W. Skey, in 1885, having been detected by him in specimens of sands obtained from streams in the south-western part of the South Island of New Zealand. Prof. Ulrich has since been able to show that the grains of this alloy are found over a considerable area, disseminated in peridotite and serpentine rocks; which rocks are intrusive in the metamorphic schists of the district, and form the Red Hill and Olivine Ranges. The substance which awaruite most closely resembles is the Oktibbehite meteorite, consisting of Ni + Fe: and the occurrence of this remarkable alloy in terrestrial rocks is comparable to the presence of nickel-iron alloys in the basalts of Ovifak and other localities in Greenland.

Exhibited by Prof. A. H. Church, F.R.S.:—A selection of Japanese sword guards, or *tsuba*, made of malleable iron, and variously decorated with chased, hammered, and pierced work, or with incrustations in gold, silver, shakudo, shibuichi, and bronze. The majority of the examples shown represent plant forms, and were executed between 1650 and 1850.

Exhibited by Prof. W. C. Roberts-Austen, C.B., F.R.S.:—Japanese art metal-work. The specimen is interesting as a modern example of flat inlaying in metals. The plate is of bronze, and the bird is of *shakudo*, or copper alloyed with a small quantity, about 2 or 3 per cent., of gold. The isolated feathers are of a darker variety of this alloy.

Exhibited by Dr. W. J. Russell, F.R.S.:—Ancient Egyptian colours discovered by Mr. Flinders Petrie in the Fayoum, and modern imitations of them; and colours from Hawara in the Fayoum.

Exhibited by Mr. A. P. Laurie:—Colours used by the fifteenth century painters.

Exhibited by Mr. W. F. R. Weldon, F.R.S. (on behalf of the Marine Biological Association):—Larvæ of certain food-fishes, together with other animals of interest inhabiting Plymouth Sound.

Exhibited by Prof. A. C. Haddon, on behalf of Mr.

A. Haly, Director of the Colombo Museum:—Some tropical fishes preserved in a mixture of gum and glycerine, as a means of displaying their natural colours. The results, although not as good as with some of the specimens located in the museum itself, represent the outcome of a series of experiments extending over a number of years, full details of which are to be found in the "Ceylon Administration Reports." Gum and glycerine have long been used in combination in microscopy, as a substitute for Canada balsam; on account, however, of the difficulty experienced with air-bubbles, their use is now very generally given up. Mr. Haly's experiments have shown that if the specimens preserved in the mixture which he employs be placed in a medium which will precipitate the gum, all colour is quickly lost, wherefore the preservation of the latter would appear to be due to the gum's influence. Mr. Haly is still prosecuting his experiments, and his latest researches show that the employment of pure glycerine for mounting (a well-nigh prohibitory condition) is no longer indispensable. He now finds that gum and glycerine are miscible with alcohol in all proportions necessary for his purposes, provided certain precautions be taken in the manipulation. He is thus enabled to check the ravages of fungoid organisms which earlier impeded his progress; and, by reducing the syrup to the necessary specific gravity with proof spirit, he is enabled to successfully preserve frogs, reptiles, and other organisms with which he originally failed, to no small degree as the result of the excessive dehydrating powers of his original medium. Mollusks, sea anemones, and jelly-fish, are among those forms of life with which the method has been least successful. Mr. Haly tells us, however, that for the Alcyonidæ his mixture is a good preservative, and that sea-water saturated with bichromate of potash has been found excellent for hardening jelly-fish. The power to preserve the natural colours of plants and animals is now the desideratum of the museum curator. Some of Mr. Haly's exhibits have stood the test of from two to three years' exposure to the light in a tropical climate. The outlook is a hopeful one; and the facts show the colonial worker, who is apt to be lost sight of in these days of competition and aggrandisement, to be fully abreast of the times, and alive to the best interests of the public.

Exhibited by the Zoological Society of London:—Eggs of a large python (*Python molurus*) laid in the Zoological Society's reptile-house. The pythons lay about thirty to fifty eggs at one time, and incubate like birds. The female python on the present occasion has "declined to sit," but on former occasions this process has been carried on in the gardens (see Proc. Zool. Soc., 1862, p. 365). Abnormal heat is developed by the sitting python as by the sitting hen.

Exhibited by Prof. A. Macalister, F.R.S.:—Two mummy heads of priests (12th and 18th Dynasties) from tombs near Assouan, Upper Egypt.

Exhibited by Sir Archibald C. Campbell, Bart:—Photographs of musical sparks, done at Blythswood, Renfrewshire, by the exhibitor.

Exhibited by Dr. Augustus D. Waller:—Demonstration of the electrical variations of the heart of man and of the dog.

The following demonstrations by means of the electric lantern took place in the meeting room:—

Animal and bird studies, photographed from life, exhibited by Mr. Gambier Bolton.

The orientation of some ancient temples, exhibited by Prof. J. Norman Lockyer, F.R.S.

Experimental demonstrations on electro-magnetic repulsion phenomena, and a series of experimental demonstrations illustrating the principal facts of the phenomena of electro-magnetic repulsion, discovered by Prof. Elihu Thomson, and their applications in alternate current electro-magnetic motors, as exhibited in the Paris Exhibition, exhibited by Prof. J. A. Fleming and Mr. Ernst Thurnauer.

THE SUNDAY SOCIETY.

ON June 21 the Sunday Society held its fifteenth annual meeting in Prince's Hall, Piccadilly. Prof. G. J. Romanes delivered his address as President of the Society. After a brief analysis of the Sunday question in general, he spoke as follows:—

As you will see from the fifteenth Annual Report which is now in your hands, the present year is one of unusual activity on the part of our Society. First of all, it has been marked by a wise stroke of policy in sending a deputation to the French Ministry for the purpose of obtaining information as to the practical results of opening the great Exhibition of Paris on Sundays. Moreover, as explained in the Report, the Committee desired to ascertain whether there be any reality in "the great bugbear of the Sabbatarian mind"—viz. that the Continental Sunday is a day of irreligion to the masses, and of overwork to the Government *employés*. As you will see from the Report, the result has been conclusively to prove the unreality of the bugbear, so far at all events as the specific question of the opening of national galleries and museums is concerned. With the more general aspects of the Continental Sunday we have not, as a Society, anything to do; but I may remark in passing that we must here remember differences of national taste and feeling. What would be irreligious levity in one community need not be so in another; and it would be absurd to attribute these differences of sentiment to differences in the matter of Sunday observance.

Next, you will find from the Report that the Trustees of the People's Palace received a memorial from the Working Men's Lord's Day Rest Association, which was promptly responded to by a counter-memorial from this Society. The latter document may best be left to speak for itself; and as it speaks with so much good English common-sense, I scarcely feel it desirable to move a vote of thanks to the Trustees of the People's Palace for having listened to us rather than to our opponents: I prefer to take it for granted that the Trustees perceive as plainly as we do on which side of this matter the truth and the wisdom lie.

Again, you will learn from the Report that, in addition to the public institutions previously opened on Sundays, several others have been this year added to the list, which now comprises 23 in all. Moreover, this year has likewise witnessed the great reform of throwing open the British Museum on certain week-day evenings; while both the authorities there and those at the National Gallery have expressed, not only their willingness, but their desire to throw open to the public on Sundays these by far the greatest of our national collections. In my opinion it is impossible for us as a Society to over-estimate the importance of having thus gained the express and cordial support of the most representative museum on the one hand, and of the most representative art gallery on the other. It now only remains that the Treasury should allow a small grant to defray the comparatively nominal expenses, and our cause would be won throughout the length and breadth of the land. For if once the British Museum and National Gallery were opened on Sundays, no other museum or art gallery could afford to resist any pressure that might be put upon them to follow so overwhelming an example. Our big guns, therefore, are at last fully charged and ready to fire; only the trigger waits to be pulled, and this it is that we are now about to attempt.

For you will observe, in the last place, that the Report in your hands contains a very weightily worded memorial which was sent to the Chancellor of the Exchequer in the middle of April. Where so many forcible considerations are comprised within so small a compass, one is much tempted to read the whole. But as other speakers are to follow me, I shall merely indicate one or two of the points in this memorial which appeal to me as of most importance.

First, then, I would have you observe how strong a ground the appeal is based upon, where it calls attention to the fact that the House of Commons has already and amply recognized the principle of their obligation to open on Sundays our national museums, galleries, gardens, &c., by having already furnished the funds requisite for the purpose to Kew, Hampton Court, Greenwich, Dublin, and Edinburgh. Again, as another very notable feature in this memorial, I may mention the enormously strong support to which it draws the attention of Mr. Goschen as having recently been given to the objects of this Society by the London County Council, who passed an almost unanimous resolution in favour of our policy. Yet once more, can anything be more calculated to sway the mind of a Minister than the anomalous state of matters to which the memorial draws attention, where it indicates that the governing bodies of the British Museum and National Gallery are expressly desirous of making arrangements whereby the priceless collections under their charge may at last become in very truth, or without any restriction, the property of the British public? When provincial institutions of incomparably less importance have already succeeded in obtaining funds from the Treasury for this purpose, is it right or fitting that the great Metropolitan institutions should be

denied a similar privilege, when their governing bodies unite with the London County Council in the petition which this memorial sets forth?

Seeing, then, that our position has now grown to be one of such well-nigh irresistible strength, I think you will all agree with me in holding that a policy which has gained such results during the past fifteen years of our existence as a Society ought to be the policy which we shall continue to follow. Having achieved this large measure of success by our quiet persistence in the way of enlightening public opinion, and patient gaining of all the strategic points of importance which we now hold, I, for one, would strongly deprecate the more noisy methods of popular agitation, with their Hyde Park processions, and so forth. But there is one piece of machinery which we have used with considerable effect on several occasions in the past; and this piece of machinery we intend once more to put into motion.

Three times in the fifteen years of its existence the Sunday Society has convened a National Conference, and in the opinion of our Committee the time is ripe for the convening of another. Therefore arrangements have been made for this the fourth Conference to meet in London during the present year. I must express my gratification that the Committee have thought fit to elect me President of the Society in a year which is thus destined to be one of unusual prominence in its annals, and I may be permitted to record my thanks for the honour which has thus been conferred, even while expressing my regret that the duty of presiding over the coming Conference has not fallen into abler hands.

As you are probably well aware, the importance of these Conferences consists in their bringing together, and combining in a collective manner, representative opinions upon the Sunday question from all parts of the kingdom. Not only are invitations issued to institutions which are already opened on Sundays to send their delegates, but statements of opinion are solicited from eminent men in all departments of science, art, and letters, as well as of public life and social organization. In this way we are able to focus the best thought of our time upon the objects which we have in view, and to deliver the result in the form of printed papers to the public, and of weighty resolutions to the Government. Time does not admit of my dwelling as fully as I should have desired upon this the most important feature of our programme for the current year, and therefore I will ask you to read an instructive historical sketch which has already been published by our Hon. Secretary, touching the work that has been accomplished by the three previous Conferences. You will find this sketch in the *Sunday Review* for January of the present year, and in order to give you a general idea of its substance, I will conclude by making two short quotations. The first I give as a sample of the opinions obtained from eminent men, and the second I give as a brief epitome of the work that we hope to accomplish by means of the fourth Conference.

The sample of opinion which I select for quotation is taken from what was said by Sir Joseph Hooker at the last Conference; and I select this expression of opinion, not only because its author, like his illustrious ancestor, is proverbially gifted with one of the best judgments that has ever helped to raise a man to the highest rank of eminence, but also because his opinion is, in this case, founded upon a statement of the most cogent facts.

Speaking as Director of the Royal Gardens at Kew, Sir Joseph Hooker said:—

"If there is one matter that gratifies me more than another, in respect of the administration of the Kew Gardens and Museums by the Government, it is the opening them to the public on Sundays. On no day of the week have we more interested visitors, or more of that class which we should wish to see profiting by the instructive contents of this institution. The Museums especially are crowded, and, when it is considered that the exhibits in them are not of articles that strike the eye or gratify the senses of colour or form, the interest they excite is almost to be wondered at. The artisan classes are great frequenters of these Museums, with their wives and families, and it is pleasing to see the delight with which the children recognize such articles as the sugar-cane, the coffee-plant and its products, and the various implements used in their preparation, manufacture, &c. I should add that this interest in the instructive character of the Gardens is largely on the increase, and is manifest to the most careless observer. It is further accompanied by a marked improvement in the conduct of certain classes, which were formerly troublesome in many ways, and a nuisance to quiet visitors. It speaks volumes for the moral effect of the Sunday opening when I add that such classes no longer exist at Kew. Whether it is that such no longer come, or that, coming, they now behave themselves, is immaterial—the moral gain is great. During the last two years we have had in each year a million and a quarter of visitors, of whom the greater proportion are Sunday afternoon arrivals from every quarter of the metropolis and its surroundings. Let the numbers speak for themselves:—1882, Sunday visitors, 606,935; week-days, 637,232. 1883, Sundays, 616,307; week-days, 624,182."

The other quotation is taken from the close of our Hon. Secretary's paper on National Conferences, already alluded to:—

"Thus the Fourth National Conference will be able to point to the friendly action of the Government in providing funds for opening the British Museum to those who desire to visit it on week-day evenings; it will have a friendly Chancellor of the Exchequer to appeal to in Mr. Goschen, who is backed up by the vote of the London County Council, and meets Parliament with a surplus which, there is a general opinion, should in part be devoted to education.

"Could education be better or more equitably promoted than by furnishing the Trustees of the National Museums and Galleries in the Metropolis with the funds necessary for throwing open these avenues of culture and refinement to the millions of people surrounding them? The people have already not only the inclination to become better acquainted with the contents of these Museums and Galleries, but they have for the most part the necessary leisure for this purpose on the fifty-two Sundays throughout the year, when the Trustees are precluded from opening them solely from want of funds, which it is just as much the duty of the Government to provide in London as outside of it, and for those who wish to visit the Museums on Sundays as well as for those who wish to do so on week-day evenings. Should the Conference make a strong appeal to Mr. Goschen, and through him to the Government, to deal justly by London in this matter, the time cannot be far distant when the reproach to the nation of having all such institutions as the National Museums and Galleries in the Metropolis closed on Sundays will be removed."

These, as I have said, are the words of our Hon. Secretary. And I cannot refer to him from the chair which I have now the honour to occupy without asking you, in conclusion, to join with me in heartily recognizing the unique value of his indefatigable work in promoting the objects of this Society. For I know it is not too much to say, that at whatever time the reproach to the nation of which he speaks will eventually be removed, its removal will have been due much more largely to one Englishman than to any other, and that the name of this Englishman is Mr. Mark H. Judge.

SCIENTIFIC SERIALS.

Studies from the Biological Laboratory of the Johns Hopkins University, Baltimore, vol. iv., Nos. 5 and 6.—No. 5 contains:—Some observations on the effect of light on the production of carbon dioxide gas by frogs, by H. Newell Martin and Julius Friedenwald. The influence exercised by light on the metabolisms of the animal body has been recognized for the last fifty years. Following up the researches of Moleschott, the authors experimentally proved that, in frogs deprived of their cerebral hemispheres, a greater quantity of carbon dioxide is given off in the light than in the dark; that, therefore, the influence of light in producing greater oxidations in normal frogs is simply reflex, and not due to greater bodily activity brought about by psychical conditions dependent on the light; that the cerebral hemispheres do not take any direct part in regulating the oxidations of the frog's body; and that this reflex action of the light, though mainly effected through the eyes, is produced partly also through the skin.—On the comparative physiological effects of certain members of the ethylic alcohol series (CH_4O to $C_8H_{18}O$) on the isolated mammalian heart, by John C. Hemmeter.—On the ventricular epithelium of the frog's brain, by A. C. Wightman. The author concludes that the epithelial layer of the frog's brain and spinal cord forms a continuous lining to the central nervous system. It is everywhere a single layer thick. The epithelium of the ventricles forms a central zone of cells, about which the brain-cells are concentrically arranged. The cells of the epithelium and of the brain are connected by processes which extend from the tips of the former. The epithelial layer consists

of cells of several varieties—the columnar, the spindle, and intermediate forms; all are ciliated.—On the temperature limits of the vitality of the mammalian heart, by H. Newell Martin and E. C. Applegarth.

No. 6 contains:—On the morphology of the compound eyes of Arthropods, by S. Watase (plates 29 to 35). In studying the structure of the ommatidium of the compound eye of Serolis it was found that it might be reduced to a simple ectodermic invagination of the skin. Extending his researches over several other Arthropods, the author found that the same interpretation could without exception be applied, and he thinks this view of the ommatidium finds its strongest support in the fact that in Limulus the ommatidium is an open pit of the skin. If these views be correct, the unit of the compound eye of an Arthropod is not so complex as has generally been conceived, and the total result is but the vegetative repetition of a similar structure. In an appendix the author alludes to his investigations into the structure of the eye in Echinoderms, the result of which he hopes shortly to publish.—On the anatomy and histology of *Cymbuliopsis calceola*, Verrill (plates 36 to 39), by J. I. Peck. A few specimens of this rare Pteropod were found in the Gulf Stream, off Cape Charles.—On the amphibian blastopore, by T. H. Morgan (plates 40 to 42), concludes that in some forms it becomes altogether or in part the neurenteric canal; in some it becomes the anus; in some, again, it closes and a new anus is formed, while he believes that in Amblyostoma it becomes both the neurenteric canal and the anus.—On a new Actinia, by Dr. Henry V. Wilson (plate 43). This new form was found on the small reef which fringes the shore of No Name Key, Abaco, Bahamas. It was discovered in a perforation on the under surface of a porites-like asteroid coral, and, though constantly looked for, but the one specimen was found. It has been called *Hoplophoria coralligens*. Below the twelve long tentacles are cycles of smaller ones, and below these four remarkable large organs, which give the animal a most *bizarre* appearance; these are diverticula of the gastro-vascular cavity, and are stinging weapons. The genus is placed provisionally with the Antheadæ.

Bulletins de la Société d'Anthropologie de Paris, tome xii. (série 3), fasc. 4, 1889.—Continuation of M. Variot's paper on pigmentation of the skin in the region of cicatrized lesions in the negro.—Descriptive ethnographic summary of the course of distribution of different races in Europe, by M. Lombard. Starting from the Neanderthal race as the only one referable to the Quaternary period, the author attempts to show that as early as the age of their descendants—the Cro-Magnon men—various alien races had already appeared contemporaneously with the latter in Central Europe. From this point, M. Lombard undertakes, on very vague premises, to trace the advance westward of successive and intersecting streams of brachycephalic and dolichocephalic peoples bringing with them their own special civilization of the dolmen, polished stone, or other, period. His view that the Pamir plateau is the cradle of the Aryans, and that they belonged primarily to the blonde races, is strongly combated by Mme. Clémence Royer, whose able refutation of his somewhat crude opinions gives to his paper its sole claim to notice.—Communications on the silex of Breonio, near Verona, and on spurious French and Italian flint implements, by M. de Mortillet, who shows the extent to which the manufacture of so-called palæontological objects is carried on.—On a case in which the gray commissure of the third ventricle was absent; and on the concomitant psychic characteristics of this anomalous condition, by Dr. F. de Marcedo.—On the mummified brain of an ancient cranium found in Venezuela, by M. Chudzinski.—On venous circulation in stumps, by Dr. Lejars.—On a rabbit with only one ear, by M. Chervin.—On the effects of the artificial deformity of the skull in a Bolivian infant, by M. Manouvrier.—On various prehistoric stations in the Department of Seine-et-Oise, by M. Vauvillé. The finds at Crespières included three implements of a sandstone not found in the district, the remainder being of cut flint. At Grancières evidence exists of the extensive manufacture of extremely small flint implements similar to those found in India, and in the neighbourhood of Tunis and Algiers, as well as in parts of South-Western Europe. The objects generally would seem to belong to the Palæolithic and Neolithic ages.—On the skeletons found at Castenedolo in Lombardy, and assumed by M. de Marcedo to be of Tertiary origin, by M. de Mortillet.—On the utility of family burying-places in reference to the study of the influence of heredity on anatomical characteristics, by Mme. Clémence Royer.—On the megalithic remains of the Department of La Somme, by M. Pouchon. The author points out the inaccuracy of the official lists published for the district, and describes a number of interesting, so-called polishing stones, and other monoliths, which demand immediate protection from the Government to save them from wanton destruction.—On the distribution of muscular force in the hand and foot, observed by means of a new form of dynamometer, by M. Féré.—Final Report of the Eighth Congress of Orientalists at Stockholm, by M. O. Beauregard.—The prehistoric stations of Coucouteni, Roumania, by M. Dimandi. The finds here are of special interest, as showing the advanced civilization of a people, probably of Greek origin, who as early as the fourth or fifth century B.C. occupied this region. The enormous number of idols, chiefly female, was a marked characteristic of the station. Besides anthropomorphic idols, a few animals, as cows and bulls, were used to represent some forms of divinities.—On the various forms of projectiles of the Neolithic age, by Dr. Capitan.—On bronze objects found in the bed of the Marne, by M. P. Masson.—On the flint knives and arrows of the Department of Aisne, by M. Vauvillé.—On the prehistoric station of Lengyel, in Hungary, by M. Nadaillac.—On a case of a pseudo-male hermaphrodite, by Dr. Pozzi.—On artificially induced deformity of the head as still practised in the Haute Garonne, and other parts of France, by Dr. Delisle (with illustrations).—Report of the Sixth Broca Conference.—On the erroneous establishment of a distinct order of true Bimana, by M. Hervé. The object of the essay is to prove that the Simians have, like man, two hands and two feet, and cannot therefore be classified as true Quadrumana, or true Bimana.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 5.—"On the Passive State of Iron and Steel. Part I." By Thomas Andrews, F.R.S., M.Inst.C.E.

The passive state of iron appears first to have been observed just a century ago by Keir, and brought before the notice of the Royal Society in 1790 (Phil. Trans., 1790, p. 379); he observed that strong nitric acid had no action on iron when the metal was placed therein. Since then, Bergmann, Schonlein, Faraday, Herschel, and others, have conducted investigations in relation to this phenomenon. In the present paper are presented the results of a study of certain magnetic, temperature, and other conditions which the author found to affect the passive state of iron and steel. The experiments of Part I. are classified under the following heads:—

Series I., containing the results of observations on the influence of magnetization on the passive state of steel in cold nitric acid, specific gravity 1·42.

Series II., treating of the influence of magnetization on the passive state of steel in warm nitric acid, specific gravity 1·42, the experiments showing that magnetized steel bars were less passive in warm nitric acid than unmagnetized ones.

The chemical composition and physical properties of the steel used are given in detail in the paper, together with the methods employed in the investigation, and detailed illustrations of the various apparatus used in course of the research. The results of the investigation are given in detail in Tables I. and II. The whole of the results on Table I. afford an indication that magnetization of comparatively low intensity, acting during considerable periods of time, exerts only a limited modifying influence on the passivity of iron or steel in the cold, though the influence is discernible when employing a delicate galvanometer. Magnetization, with the nitric acid at a higher temperature, produces a quicker effect (see results in Series II., Table II.). In a recent research by the author "On Electro-chemical Effects on Magnetizing Iron, Part II." (Roy. Soc. Proc., vol. xliv. p. 152), it was noticed that local currents were set up between the polar terminals and central portions of steel magnets exposed as electrolytes; and this class of local action, together with the slight alteration of the physical structure of the magnet bars consequent on their magnetization, may possibly be involved in producing the effects due to magnetism on passive steel or iron in conc. nitric acid.

"Observations on Pure Ice, Part II." By Thomas Andrews, F.R.S., M.Inst.C.E.

The experiments contained in the paper form a continuation of a previous research by the author. The experiments were

made to investigate the relative plasticity of pure ice at various temperatures ranging down to $-35°$ F., and also of pond ice. The arrangements of apparatus used in determining the plasticity of pure ice and pond ice are illustrated in detail in the paper. The ice for the pure ice experiments was frozen from distilled water; the coolest freezing mixture used, consisting of three parts by weight of crystallized calcium chloride and two parts by weight of snow, yielded a constant temperature of $-35°$ F.; other freezing mixtures were used for the temperatures above this. The cylinders of pure ice employed were 2 feet 1½ inch long, and 2 feet 1½ inch diameter, and weighed 470 pounds. The plasticity was ascertained by measuring the relative penetration, during equal periods of time, of the polished steel rods into the ice, care being taken to avoid errors from conductivity. A large number of experiments were also made on the plasticity of natural lake or pond ice. The influence of the composition of water on the plasticity of the ice frozen therefrom was investigated, and a number of experiments were made to ascertain the proportion of the saline constituents of the lake water taken up into the ice during crystallization. Roughly speaking, it was found that the proportion of inorganic matter in the melted ice was about ten per cent. of the total inorganic salts contained in the lake water from which it was frozen. The general summary of results of the experiments on the plasticity of pure ice at the various temperatures employed are plotted out in four curves on Diagram I., and the results of the experiments on the plasticity of pond ice are shown in detail on Diagram II. In the majority of instances, it was found that, if the plasticity of the ice at $-35°$ F, be called 1, at 0° F. it would be about twice as much, and at 28° F. the plasticity would be about four times as great as at 0° F., or eight times as much as at $-35°$ F. The comparatively great contractibility in ice observed at considerably reduced temperatures (see the author's former paper "On Observations on Pure Ice and Snow," Roy. Soc. Proc., No. 245, p. 544) may probably account for the great reduction in its plastic properties at low temperatures. This is in accord with the practical cessation of motion in glaciers during the cold of winter. It was also noticed in course of the research that the plasticity of the naturally frozen pond ice was manifestly greater than that of the prepared pure ice; the comparative difference in the behaviour of the pond ice was doubtless owing to a portion of the saline constituents of the water interspersing during congelation between the faces of the individual crystals of ice, thereby tending to reduce the cohesion of the mass as a whole, and increasing its plasticity.

Linnean Society, June 5.—Prof. C. Stewart, President, in the chair.—The President nominated as Vice-Presidents for the year Messrs. W. Carruthers, P. Martin Duncan, J. G. Baker, and F. Crisp.—Mr. H. Little exhibited and made some remarks upon a photograph of a remarkable Aroid, *Amorphophallus titanum*, which had flowered for the first time in this country.—Mr. James Groves exhibited a specimen of an *Orobanche* parasitic upon a *Pelargonium*.—The following papers were then read and discussed:—On a collection of plants made in Madagascar, by Mr. G. F. Scott Elliot.—On Weismann's theory of heredity applied to plants, by Rev. G. Henslow.—Teratological evidence as to heredity of acquired conditions, by Prof. Windle.—On the development of the tetrosporangia in *Rhabdochorton Rothii*, Naegeli, by Mr. Harvey Gibson.—On the position of *Chantransia*, with a description of a new species, by Mr. George Murray and Miss E. Bass.—On the development of the cystocarp in *Callophyllis laciniata*, by Miss A. L. Smith.—On the cystocarps of some genera of Florideæ, by Mr. J. B. Carruthers.

Royal Meteorological Society, June 18.—Mr. Baldwin Latham, President, in the chair.—The following papers were read:—On the difference produced in the mean temperature derived from daily maximum and minimum readings, as depending on the time at which the thermometers are read, by Mr. W. Ellis. In the publications issued by the Greenwich Observatory authorities, the maximum and minimum temperatures are those referring to the civil day from midnight to midnight. At many stations the observers only read their instruments once a day, viz. at 9 a.m., when the reading of the maximum thermometer is entered to the preceding civil day, and the reading of the minimum thermometer to the same civil day. Such stations are called "climatological stations." The author has tabulated the Greenwich maximum and minimum temperatures according to both methods for the years 1886-89, and finds that the climatological maximum and minimum means are in excess of the civil day means.—On the distribution of barometric pressure at the average level of the hill stations in India, and its probable effect on the rainfall of the cold weather, by Mr. W. L. Dallas. The weather over India during January 1890 was very dry, and in marked contrast to that which prevailed during January 1889. The distribution of barometric pressure was, however, much the same in both months. The author has investigated the records at the hill stations, and has prepared charts showing the distribution of barometric pressure from both high and low level stations. From the high level charts it appears that the mean barometric gradient in 1889 was rather more than twice that in 1890, and, considering what is known of air movements, even at moderate elevations above the earth's surface, it may be assumed that these differences in pressure were accompanied with large differences of air motion; and if it is also assumed that the evaporation over the Southern Ocean is in all years fairly comparable in amount, the deficiency of rainfall over India in the winter of 1889-90 can be attributed to diminished lateral translation of vapour owing to sluggish movements in the upper atmosphere.—On the relative prevalence of different winds at the Royal Observatory, Greenwich, 1841-89, by Mr. W. Ellis. The author gives the following as the average number of days of prevalence of different winds for the 49 years 1841-89, as derived from the records of the self-registering Osler anemometer:—

N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.	Calm.
40	45	27	22	35	106	46	22	22

—On some recent variations of wind at Greenwich, by Mr. A. B. MacDowall.—On the action of lightning during the thunderstorms of June 6 and 7, 1889, at Cranleigh, by Captain J. P. Maclear, R.N. The author examined a number of trees which had been struck by lightning during these thunderstorms, and found that those which were struck before the rain fell were shattered, while those which were struck after the rain commenced were simply scored, with the bark blown off. It seems that during rain every tree is conducting electricity, and a disruptive discharge takes place where the conductor becomes insufficient. This depends on the position of the cloud, the amount of foliage on the tree, its condition of moisture, and its connection with running water.

Geological Society, June 4.—Dr. A. Geikie, F.R.S., President, in the chair.—The President referred to the sad loss which the Society had sustained through the death of Mr. Dallas, and read the following resolution, which had been passed by the Council and ordered to be entered upon its minutes:—"The Council desires to record on its minutes an expression of its deep regret at the death of the Assistant-Secretary, Mr. Dallas, which took place on the 29th ultimo, and of its sense of the loss inflicted on the Council and Society by the removal of one who, for the long period of twenty-two years, had done them invaluable service, and who, by his courtesy, kindliness, and helpfulness had endeared himself as a personal friend to the Fellows." It was moved by Dr. Evans, seconded by Dr. Hinde, and carried unanimously, that the resolution passed by the Council be communicated to Mrs. Dallas on behalf of the Society also.—The following communications were read:—As to certain "changes of level" along the shores on the western side of Italy, by R. Mackley Browne.—North Italian Bryozoa, by A. W. Waters.—Notes on the discovery, mode of occurrence, and distribution of the nickel-iron alloy "Awaruite," and the rocks of the district on the West Coast of the South Island of New Zealand in which it is found, by Prof. G. H. F. Ulrich. In an introduction, the author describes the original discovery, determination, and naming of the mineral in 1885 by Mr. W. Skey, and clears up a misunderstanding by which he himself had been credited with the discovery; he furthermore gives a historical sketch of the further investigations and publications referring to the mineral. The geology of the Awaruite-bearing district is described. The rocks consist of peridotites and serpentines, breaking through metamorphic schists with occasional massive intrusions of acid rock. The petrographical characters of the peridotites of the hill-complex, including the Olivine and Red Hill Ranges, and serpentines are considered in detail, and the mode of occurrence of the Awaruite in them and in the sands derived from their denudation is discussed. The author submits a sketch-map of the localities where the mineral has been discovered in sand, including not only George River, but also Silver Creek, Red Hill, and other localities, and quotes Mr. Paulin's belief that it occurs diffused

through the whole extent of peridotite and serpentine rocks, and inferentially in the drifts derived therefrom. The President noted the interest attaching to the gradual development of our knowledge of native iron of terrestrial origin. Prof. Judd was glad to have the present opportunity of removing a misconception that had arisen concerning this mineral. In bringing the matter before the Society on a previous occasion he dwelt upon the facts of special geological interest, and Mr. Skey's name was not mentioned in the few lines placed on record in the Proceedings. No attempt, however, had been made by Prof. Ulrich to claim the discovery of this mineral, though he appeared to have been the first to record its peculiar occurrence in the ultrabasic rocks. In the South Island was the well-known chromite-bearing olivine rocks of the Dun Mountain, but the rock now described was in a distant part of the same island. An interesting series of serpentines derived from peridotites has been sent over by the author, and these specimens contain the "Awaruite." A number of garnets and chlorites, with chrysotile, talc, and magnetite, have been found in the Red Hills. He was not aware that any "Awaruite" had been discovered in the peridotite; but this was probably due to the softer nature of the serpentine, where it could be more easily detected. He had recently heard that one of the serpentines of Norway had yielded a similar alloy.

Edinburgh.

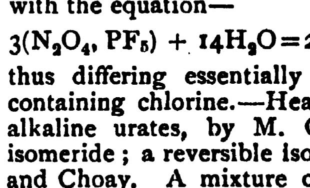
Royal Society, June 2.—Sir Douglas Maclagan, Vice-President, in the chair.—Prof. Crum Brown read a paper on the relation of optical activity to the character of the radicals united to the asymmetric carbon atom. He stated that—if we denote the optically active compound by the symbol C(ΑΒΓΔ)—where C denotes the carbon atom, and Α, Β, Γ, Δ denote the radicals arranged in order of a hitherto undetermined quantity, K—any replacement of one of the radicals by a new one which changes the order as regards K alters the sense of the optical activity. Suppose, for instance, that as seen from Α the values of K for Β, Γ, Δ are in ascending order. If we substitute for Γ an atom whose K is greater than that of Δ, the order will now be Β, Δ, Γ′, which is left-handed if that of Β, Γ, Δ was right-handed. Thus (assuming that increase of *mass* is accompanied by increase of K), he finds that in a number of such compounds the alteration indicated produces a substance in which the direction of rotation of the plane of polarization of light is reversed.—Dr. H. R. Mill read a paper on the mean level of the surface of the solid earth, in which he showed that, from Dr. John Murray's calculations, the general level of the lithosphere was at a depth of 1400 fathoms beneath mean sea-level. More recent explorations show that the oceanic depths are deeper and more extensive than was formerly supposed, so that the mean sphere-level—the surface of a shell which cuts the slope between the elevated and depressed region of the earth's surface in such a manner as to leave a volume of elevated material above it exactly equal to the volume of the depressed region beneath it—appears to lie close to a depth of 1700 fathoms. The contour line of 1700 fathoms of ocean depth divides the earth's surface into two equal areas—one of depression, the other of elevation. This remarkable coincidence shows that the portions of the elevated half of the lithosphere projecting above mean sphere-level would just suffice to fill the hollow beneath mean sphere-level of the depressed half. Dr. Mill also pointed out that round the edge of the great three-armed northern elevated mass the slope to the depressed area was so steep that the outlines of the 1000 and 2000 fathom contours follow the coast-line very closely; but the Antarctic elevation rises from the bed of the depression with an extremely gentle slope.—Mr. J. Crockett communicated an account of Weierstrass's contributions to the calculus of variations.—Mr. John Anderson gave accounts of the recent Louisville tornado, and showed a barometric record made in its neighbourhood. The barometer fell suddenly to the extent of about one-tenth of an inch, and again instantly rose as the tornado passed.

Paris.

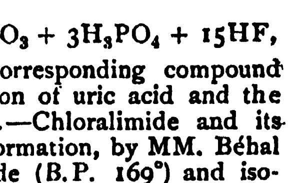
Academy of Sciences, June 16.—M. Hermite in the chair.—On the ordnance survey of France, by M. Maurice Lévy. In commenting upon the work undertaken by the Geodetical Commission, M. Lévy notes that two kinds of documents will be published—one to contain an account of the methods of calculation and corrections which have been employed, as well as the description of the instruments used; the other to be a graphical *répertoire* of the levels determined—and in presenting an account of the first series of operations, some explanation of the work is given.—Theory of the permanent movement produced near the widened opening of a fine tube; application to the second series of Poiseuille's experiments, by M. J. Boussinesq.—Calculation of the successive temperatures in an indefinite homogeneous and athermanous medium which is in contact with a source of heat, by the same author.—On the various isomeric inosites and their heat of transformation, by M. Berthelot. The author finds that in dextrorotatory inosite, dehydrated and having the formula $C_6H_{12}O_6$, dissolved in 300 c.c. of water at 17°·9, the heat absorbed by 1 molecule is − 2·05 calories. Lævorotatory inosite similarly treated gives − 2·03 calories. On mixing the two liquids no rise or fall of temperature was observed. It is therefore concluded that two symmetrical inosites do not show any signs of combination when in solution. Four grammes of neutral inosite were dissolved in 300 c.c. of water at 18°. The rate of solution was slower than that of the active inosites, and the heat developed was − 3·87 calories. This heat of solution is negative and greater than that of either of the active inosites. The three corresponding tartaric acids give the same results.—Variation of the elasticity of glass and of crystal with temperature, by M. E. H. Amagat. It appears from the experiments that the variation increases with the temperature; it is a little greater for glass between 100° and 200° than between 100° and 0°, and considerably greater in the case of crystal; and it seems probable that the variation would increase more and more in value with still higher temperatures.—On a new property of luminous waves, by M. Gouy.—Characteristic equation of hydrogen, by M. Ch. Antoine.—On the variation of temperature with altitude in cyclones and anticyclones, by M. Marc Dechevrens. From a series of observations the law is formulated that "at sea-level and in air, at an altitude less than 1000 or 1200 metres, the temperature in a vortex varies inversely as the pressure, whilst in air at greater altitudes it varies directly as the pressure. In the latter case the temperature has a minimum along the axis of the cyclone and a maximum on the perimeter of the depression; a maximum also occurs along the axis of an anticyclone."—On the combinations and reactions of the gases ammonia and phosphoretted hydrogen with the halogen compounds of arsenic, by M. Besson. The compounds $AsBr_3.3NH_3$; $AsCl_3.4NH_3$; $AsI_3.4NH_3$; and $2AsF_3.5NH_3$ are described, and the products of their decomposition indicated.—On a new method of forming crystalline oxychlorides of the metals; researches on the oxychlorides of copper, by M. G. Rousseau. Among other bodies of the same type, the author has succeeded in obtaining crystallized *atacamite* by his method.—On the combination of phosphorus pentafluoride with nitrogen tetroxide, by M. Emile Tassel. The body formed, $N_2O_4.PF_5$ reacts with water in accordance with the equation—

$$3(N_2O_4, PF_5) + 14H_2O = 2NO + 4HNO_3 + 3H_3PO_4 + 15HF,$$

thus differing essentially from the corresponding compound containing chlorine.—Heat of formation of uric acid and the alkaline urates, by M. C. Matignon.—Chloralimide and its isomeride; a reversible isomeric transformation, by MM. Béhal and Choay. A mixture of chloralimide (B.P. 169°) and isochloralimide (B.P. 103°–104°) is obtained by the action of heat upon chloralammonia; the method of separation and purification of each of these bodies is described. Both bodies possess the same molecular weight, Raoult's method with benzine for solvent yielding the figures—for chloralimide 430, for isochloralimide 434–435. Each body may be transformed by suitable means, given in detail, into its isomeride. The following formulæ are proposed by the authors as representations of these bodies:—



Chloralimide.



Isochloralimide.

—On an adulteration of linseed oil, by M. A. Aignan.—On the ear gland (*Paludina vivipara*) and the nephridian gland (*Murex brandaris*), by M. L. Cuénot.—Researches on multiple buds, by Mr. William Russell. The conclusion is drawn that "multiple buds, one springing from another and being vascularly

connected therewith, ought to be considered as normal ramifications."—On the influence exercised by the time of cutting upon the production and development of shoots from the stocks in underwood, by M. E. Bartet.—Influence of the peritoneal transfusion of the blood of the dog upon the evolution of tuberculosis in the rabbit, by MM. J. Héricourt and Ch. Richet.—On the antiseptic and antipeptic doses of various substances, by M. Andrea Ferranini.

BERLIN.

Physiological Society, June 6.—Prof. du Bois-Reymond, President, in the chair.—Dr. Hagemann gave an account of his experiments on proteid metabolism during pregnancy and lactation; they were conducted upon two dogs supplied with a constant nitrogenous diet. During the first half of the period of pregnancy more nitrogen was excreted than was taken with the food, so that the nitrogen requisite for the growth of the fœtus must have been derived from the tissue-proteids of the mother. After this period the nitrogenous excretion sank to a condition of equilibrium in the middle of pregnancy, and then fell further until the birth of the offspring. Immediately after parturition there was a very marked increase in the excretion of nitrogen, followed by a sudden fall which led to the output being, during four weeks' lactation, less than the in-take.—Prof. Zuntz made a further communication respecting the intestinal fistulæ which he described at the previous meeting of the Society. As regards the absorption of fats and fatty acids, he found that even the finest and most uniform emulsions were not absorbed either alone or with the addition of bile. When saponified, a marked absorption of the soaps took place, but to a much less extent than in normal animals; neither was it increased by the addition of glycerine. The results obtained were, on the whole, negative. The speaker put forward the view that the absorption of fat in the intestine is dependent upon some at present unknown function of the pancreas.

AMSTERDAM.

Royal Academy of Sciences, May 31.—Mr. Max Weber pointed out the characters of a true adult hermaphroditic finch (*Fringilla cœlebs*), caught in the neighbourhood of Amsterdam. The right side of the bird has the plumage of the adult male, the left that of the adult female. The striking difference in the colouring of the plumage on the two sides corresponds to an internal co-existence of ovary and testis: the latter is, on the male-coloured (right), the former on the female-coloured (left) side. Both sexual glands, compared, also microscopically, with the testis and ovary of normal finches, are anatomically wholly normal, and able to produce male and female sexual elements. The case seems to be an illustration of the dependence of sexual colouring upon the nature of the sexual gland.—Mr. van Bemmelen stated that Mr. Molengraaff had sent him a white substance found in the high moor of Drenthe (Netherlands), denominated by the moor-diggers as *White Klien*. It consists of 87 per cent. carbonate of oxydulated iron, 6 per cent. carbonate of lime, and 8 per cent. vegetable matter.—Prof. Hubrecht gave a description of the early developmental stages in the shrew. In the two-layered blastocyst the mesoblast makes its appearance: (*a*) from the hypoblast under the anterior portion of the epiblastic shield; (*b*) from the primitive streak and its anterior prolongation; (*c*) from an annular zone of hypoblast below, but just outside the border of the epiblastic shield. The mesoblast from these three sources very soon fuses into one continuous plate. There appears to be considerable agreement between the facts as presented by the shrew and those which Bonnet has described for the sheep. The gastrulation process in the Mammalia was then comparatively considered, and a theoretical interpretation put forward, differing considerably from E. van Beneden's latest hypothesis.

STOCKHOLM.

Royal Academy of Sciences, June 11.—Spiders from the Nicobar Islands and other parts of Southern Asia, mostly collected during the voyage of the Danish war-ship *Galatea* in the years 1845–47, described by Prof. T. Thorell.—On the remains of a fish preserved since the year 1289 in the cathedral of Wisby, and often mentioned in the old chronicles as a remarkable curiosity, by Prof. F. A. Smitt.—Étude des conditions météorologiques à l'aide de cartes synoptiques réprésentant la densité de l'air, par Dr. N. Ekholm.—On an expedition which has just started for Spitzbergen, by Baron A. E. Nordenskiöld. This expedition consists of some young Swedish naturalists who propose to make geological and zoological researches.—On the fungi of Omberg and its neighbourhood in Ostrogothia, by Herr L. Romell.—On the different kinds of vegetation on the surface of the peat bogs of Southern Sweden, by Herr G. Andersson.—Dendrological studies made in several Swedish provinces, by Herr F. Laurell.—On the vegetation of Norrbotten, by Dr. A. Lundström.—Botanical rambles in the south-west of Jemtland in the summer of 1889, and description of some Hieracia and Carices found, by Dr. M. Elfstrand.—On the oxidation of the phenyl-methyl-triazol-carbon acid, i., by Dr. J. A. Bladin.—On some ammoniacal platina combinations, by Dr. O. Carlgren.—Critical remarks on the history of the vegetation of Greenland, by Prof. A. G. Nathorst.—Studies on the Turbellaria and Nemertinæ of the northern countries, by Dr. D. Bergendal.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Catalogue of Stars observed at the U.S. Naval Observatory during the Years 1845–77, 3rd edition: Prof. M. Yarnall and Prof. E. Frisby (Washington).—Father Perry, F.R.S.: A. L. Cortie (Catholic Truth Society).—Travels in Africa during the Years 1875–78: Dr. W. Junker, translated by A. H. Keane (Chapman and Hall).—Nitrogen: its Uses and Sources in Agriculture: C. M. Aikman (Glasgow, Wright).—A Handy Guide to the Birds in the Bootle Museum: J. J. Ogle (Bootle).—Record of Experiments in the Production of Sugar from Sorghum in 1889: H. W. Wiley (Washington).—A Revised Account of the Experiments made with the Bashforth Chronograph to find the Resistance of the Air to the Motion of Projectiles: F. Bashforth (Cambridge University Press).—Selected Subjects in Connection with the Surgery of Infancy and Childhood: E. Owen (Baillière).—The Triumph of Philosophy: J. LIFE OF SEDGWICK.

I.

The Life and Letters of the Reverend Adam Sedgwick, LL.D., D.C.L., F.R.S., Fellow of Trinity College, Cambridge, Prebendary of Norwich, Woodwardian Professor of Geology, 1818–73. By John Willis Clark, M.A., F.S.A., and Thomas McKenny Hughes, M.A., F.R.S. Two Volumes. (Cambridge: University Press, 1890.)

BETTER late than never! Geologists have waited for seventeen years for a life of Sedgwick, though the biographies of Murchison, Lyell, and Darwin, two of whom survived him, have all been published. The delay, as is admitted in the preface, requires some explanation: whether that is really furnished may be doubted. This at least is clear, that it has not been due to Mr. Clark, since he only undertook his portion of the work, and that the major one, in 1886. The delay is the more to be regretted because not a few of those who could remember Sedgwick in the days of his full vigour have passed away, and, as Mr. Clark observes, "a number of interesting letters which he is known to have written, and which were long carefully preserved, have either been destroyed or cannot now be traced. These remarks apply specially to the earlier years." Still, Mr. Clark has had at his disposal a large amount of material, from which he has drawn a picture no less vivid than accurate—as we feel sure those who knew the original will admit—of a man of remarkable genius and almost unique personality. He has told us the story of Sedgwick's life, he has woven into it Sedgwick's letters, and the result is a book which is worthy to be classed with the two best biographies, at any rate of recent date, of distinguished sons of Cambridge—those of Charles Kingsley and Charles Darwin.

This book has its value as a chronicle of the development of geology into a distinct and independent branch of science, but this is not its only interest. True, it is a record of a life comparatively uneventful. It was not often that Sedgwick's geological studies conducted him beyond the limits of the British Isles. His Continental journeys were restricted to the western half of Europe, and did not include Spain or Scandinavia, but his friends were numerous and notable. His life extended over a period of our national history of unusual interest. He remembered vividly the great incidents of the "struggle for life and death with France." He heard the death peal rung for Nelson and for Wellington: he had shared in the domestic strife of the Reform Bill, and had witnessed the blunders of the Crimea and the peril of India. His sympathies were as quick as they were wide, and he was not only a frequent letter writer, but also a master of that almost forgotten art. Hence these volumes contain much that will be interesting to others than geologists. They are the record, not of a life devoted solely to one special study, but of a man of varied interests and rare enthusiasm, of unusual eloquence and exceptional descriptive powers. Not the least valuable part of the work is Sedgwick's own account (extracted from a privately printed pamphlet) of the manners and customs of the dalesmen of the Sedbergh district, among whom he was born, whither he constantly returned, and which he loved to the last hour of his life.

This book brings before us Sedgwick as a man and as a geologist, a division which corresponds with the work of its joint authors. Though the two characters made up the one personality, and a distinction between them must be to some extent arbitrary, this may be adopted, as a matter of convenience, in endeavouring to give some idea of the varied contents of these volumes.

Adam Sedgwick was born in the year 1785, the fourth child of the Rev. Richard Sedgwick, vicar of Dent, an old-world village, by a tributary of the Lune, among the great hills of Western Yorkshire. He was a member of one of the families of "statesmen" which had been settled in Dent for more than three centuries. Till he was sixteen years old he was taught at the Grammar School, partly by his father; then he was sent to school at Sedbergh; thence he went, in his twentieth year, to Trinity College, Cambridge, after a few months' tuition by John Dawson, a country surgeon (he had ushered Sedgwick into the world) who had become eminent as a mathematician, as teacher no less than as investigator. Sedgwick's work at Cambridge was interrupted by an attack of typhoid fever which nearly proved fatal, but, notwithstanding this, he obtained a scholarship in his College, and the fifth place among the Wranglers in the Mathematical Tripos of 1808. Private pupils and reading for his Fellowship employed him for the next two years, the latter being obtained in the year 1810. The double work proved a severe strain to Sedgwick's constitution. The great importance which has always been attached at Trinity College to the examination for fellowships has its advantages and its disadvantages; the one as affording an opportunity for remedying ill-fortune at the time of the degree and widening the field of choice; the other as giving an advantage to the wealthy, and pressing heavily on those who must combine work for a living with study for an examination. Not a few of the latter have paid for success by permanent injury to health. Among these, it appears, Sedgwick must be reckoned. During the next three years he was out of health, and in 1813 came a complete breakdown. Consumption was apprehended; but at last his naturally strong constitution triumphed, and he was able to return to Cambridge and take part in the regular tuition of the College. In 1816 he was ordained. Three years later came the great crisis of his life—the Woodwardian Professorship of Geology, hitherto little more than a sinecure, became vacant, and Sedgwick declared himself a candidate. His prospects of success at first did not seem great, for he had little, if any, knowledge of the subject, and was opposed, not only by a member of his own College, but also by the Rev. G. Gorham, of Queens' College, who was reputed to have devoted much attention to geology, though he does not appear to have published anything. But the opponent from within the walls of Trinity retired, and then Sedgwick had an easy victory over the other. Cambridge—perhaps Oxford also—has often been rather eccentric in her elections to professorships, and prone to act on the maxim "*Omne ignotum pro magnifico.*" But on this occasion the leap in the dark was more than justified.

Neither of Sedgwick's opponents afterwards made any name as geologists, though the second of them lived to fight a battle for religious freedom in the Church of England.

At once Sedgwick threw himself heart and soul into his subject. Geology at that time signified little more than an excrescential growth from mineralogy, which became the less scientific the further it departed from its support. Still, the Geological Society of London had already been founded full ten years; and the men were now hard at work who were to roll away the reproach from geology, and lay its foundations on the sure ground of observation and induction. Neptune had failed to extinguish the torch of Pluto, and the Wernerians were retreating before the Huttonians; William Smith had already published his wonderful maps, and had set in order, almost single-handed, the newer rocks of England; but below the base of the Carboniferous system a great field for research still remained, in which the generation of Sedgwick's more immediate contemporaries were destined to win their laurels.

Sedgwick's first geological journeys were in Derbyshire and Staffordshire, in the Isle of Wight, and on the coast of Suffolk. But the learner quickly became an investigator. Even in 1818 he began to attack the problems presented by the older rocks of the south-west of England; thence he turned aside to examine Eastern Yorkshire and Durham. Difficult problems seemed from the first to have for Sedgwick a peculiar fascination, and in 1822 he grappled with those presented by the Lake District. In 1827 began his association with Murchison, whom he accompanied in a geological tour to Scotland, and joined in a paper on the results. The following summer saw them companions in their notable researches in Germany and the Tyrol, which produced another joint communication. By this time Sedgwick's merits had been recognized by his election to the Presidency of the Geological Society.

The year 1831 brought two important crises in Sedgwick's life—the one the offer of a valuable living from the Lord Chancellor, the other the beginning of his work in North Wales. That offer he declined, making a mistake, as several of his friends thought—an opinion to which his biographer inclines. Probably Sedgwick would have been a healthier man in a country rectory—for the climate of Cambridge was not suitable to him—and a happier man in married life. But science, we think, would have lost. It might not have been so with some men, but it was Sedgwick's nature to throw himself with all his heart into whatever work he undertook; so that in all probability the interest felt for his parishioners and his home circle would gradually have extruded geology from his thoughts. In this case science would have had to wait some time for the unravelling of much complicated stratigraphy; the collections of the Woodwardian Museum might have remained in a comparatively impoverished condition, and the University would have lost the quickening action of Sedgwick's influence on generations of its students.

Next year Sedgwick took a new departure in authorship. A College Commemoration sermon, which he had been asked to print, increased under his hands, with a prefatory head and a commentarial tail, till the "Discourse on the Studies of the University of Cambridge" expanded into a book, and became, as he phrased it, "a grain of wheat between two millstones." In 1834 he was made a Prebendary of Norwich, a preferment which, though its duties often seriously interrupted his scientific work, was a welcome addition to his income, which up to that time had hardly sufficed for the numerous calls upon it.

For the next six years his work in the field was less and his papers rather fewer; henceforth interruptions obviously became more frequent. The rearrangement of his fine geological collections, for which at last a museum had been provided; political incidents, in which he took an active interest; visits to and from distinguished friends, which became more numerous as his fame increased—all these proved, as they always prove, detrimental to work which requires steady and continuous application. But as the scientific interest of the book wanes a little, its general interest increases. Graphic sketches of notable personages appear more frequently in Sedgwick's letters, which come nearer to being a journal of his life. They bring out also—for many of them are written to young folks—all the tenderness of his nature: they intersperse fatherly advice with accounts of his doings, now grave, now comic. One moment he pulverizes a scientific foe; the next, gives his niece a ludicrous lesson on the pronunciation of Welsh. The election of Prince Albert to the Chancellorship of the University of Cambridge, in which Sedgwick took a leading part, still further interfered with his devotion to science, for it led to his acting as the Prince's secretary in Cambridge, and holding a place on a Commission for the Reform of the University. This, however, is a gain to the book, for his private letters give many interesting details of the Royal visit to Cambridge, and especially of the home life of the Queen and Prince Albert at Osborne.

After a time, about the year 1851, the Silurian question, presently to be noticed, spurred Sedgwick into renewed activity in his old field of work, but led to the unhappy result of his alienation from Murchison and his estrangement from the Geological Society. The burden of years, however, was now beginning to make itself felt, for in 1855, when he reviewed the controversy in his introduction to McCoy's "Description of British Palæozoic Fossils," he attained the age of threescore and ten. Henceforth the path of his life became sadder; one by one friends passed away, the infirmities of age increased, and though at times the old fire flashed up, and for a while the racy phrase and eloquent speech would return, he now felt, as most must feel, something of the *pœna diu viventibus*. Still he was able, up to about 1863, to take occasionally an active part in passing events, though more and more he was compelled to avoid excitement and fatigue, and thus his life at Cambridge was often lonesome. During the last ten years he sometimes suffered severely; almost he might have described himself as "sans teeth, sans eyes," sans ears, though happily not "sans everything," for the mind, as his letters show, continued unclouded, though, of course, sometimes that memory, once so marvellously retentive, failed a little. No part of the book is more tender, none more sympathetic, than the account of Sedgwick's last years. Early in 1873 came the closing scene, in the rooms in Trinity, which had been for so many years his chief home.

"There was no change till about midnight," writes his niece, "and then we saw the shadow of death come softly over his face, and we knew that he had passed into the dark valley, and that the end was near; but there was no pain; only quiet sleep. His breathing again grew more faint and soft; and without a sigh, just as the clock in the great court of Trinity chimed a quarter past one, his spirit returned to God."

Sedgwick's original scientific work will be sketched in another notice. This may conclude with a word on the man himself. A stalwart figure with rugged features and brown complexion, a flashing eye, and a grand pose of the head, which always reminde me of an eagle. He called himself—men called him—ugly. This I never could understand. Few were better tellers of a story: his memory of striking details, his sense alike of humour and of pathos, were so strong. As a lecturer he was discursive, but suggestive—one who stimulated and fertilized rather than who trained. His speeches were marked by a curious play of fancy, unexpected transitions from grave to gay, and occasional bursts of eloquence, which our greatest orators might have been glad to own. As a writer he was often diffuse, sometimes laboured—the results of hurried work or unsystematic arrangement; yet he broke out occasionally into passages of singular force and vigour. For instance, the concluding paragraphs of his preface to the "Catalogue of Cambrian and Silurian Fossils"—his last contribution to literature—are worthy, in my judgment, of a place among the best extracts from English literature. He was sometimes strong and even narrow in his prejudices, as will appear hereafter; he was impetuous in temper, fierce in the fray, positively ripping up an incompetent antagonist; yet he was commonly the most genial and placable of men; he was tender as a woman to those who sorrowed and who suffered, and was the idol of little children.

We may close the present notice with the words with which Mr. Clark concludes his own part of the biography—the words of one of Sedgwick's intimate friends:—

"He was transparent and straightforward—the very soul of uprightness and honour—tender and affectionate—most generous and kind. He had a hatred of all duplicity and meanness. He was entirely unsuspicious of evil, unless it was forced upon his notice; and he expected and believed everyone to be as straightforward and truthful as he was himself. I do not think that any man was so beloved by his friends as he was."

T. G. BONNEY.

(*To be continued.*)

GÉRARD'S "ÉLECTRICITÉ."

Leçons sur l'Électricité, professées à l'Institut Électrotechnique Montefiore annexé à l'Université de Liège. Par Eric Gérard, Directeur de cet Institut. (Paris: Gauthier-Villars, 1890.)

THE author of this book says in his preface that when he took charge of the classes in electric technology at Liége he felt the want of a text-book which would give a clear and definite account of electrical phenomena without requiring more extensive mathematical knowledge than his pupils might be expected to possess. We think that in this respect the experience of most teachers of electricity will coincide with that of M. Gérard. There are very few text-books on electricity in which the happy mean between utter vagueness and methods requiring the use of high mathematical knowledge has been hit; this, however, has been done so successfully in the book before us, that we think the difficulty to which we have just alluded will be almost removed. In this book we have the main outlines of electricity explained in language at once intelligible and precise, and without introducing more mathematics than every student of the subject ought to be competent to follow. In a subject like electricity, where forces have to be compared, the geometrical properties of bodies of various shapes utilized, &c., it is evident that if any numerical results at all are to be attained, some mathematics must be introduced; the question as to how much mathematical knowledge should be expected of students who, as a working hypothesis, may be assumed not to have any special aptitude for that study is one on which opinions will differ. For our part, we think that, even regarding it solely from the point of view of the engineer or physicist, such students ought to be advised to acquire an elementary knowledge of the differential and integral calculus; the possession of this knowledge will make many parts of the subject easy which without it would be difficult, and the time spent in acquiring the mathematics will be much more than saved in the time spent over the physics. In the book before us the mathematics are as plain and straightforward as possible. At the same time, M. Gérard, very wisely we think, does not scruple to use the elements of the differential and integral calculus.

The work contains more than 500 pages, of which about 200 are devoted to the theory of Dynamos. The remainder consists of an exceedingly clear and accurate description of electrical phenomena, the subject throughout being treated from Maxwell's point of view. The book is brought well up to date, and contains an account of most of the recent researches in electricity and magnetism; we think, however, it would have been improved by references to the places of publication of the original papers in which these researches are described, so that a student who wishes for a more detailed description than could be given in an elementary text-book might be able to refer to the original authorities for himself.

A most excellent feature of the book is that M. Gérard does not treat the subject as if an investigation was complete when it had led to a relation between a number of symbols. He applies the equations he gets to actual cases, and thus familiarizes the student with the magnitude of the quantities with which he is dealing. He commences the book with Sir William Thomson's maxim, which is so excellent in physics, though its application to other subjects might possibly cause consternation, that "we cannot understand a phenomenon until we can express it in numbers," and he acts up to the spirit of this maxim all through the book.

The book is well and clearly printed, and the author has realized the fact that it is more important that the diagrams in a text-book of physics should be explanatory than that they should be elegant.

There are one or two points which we think might be corrected in a new edition, which we are sure will soon be required. The deformation of dielectrics under elec-

tric forces, which is cited as a proof of Maxwell's theory of stress in the medium, is rather an obstacle than a support to the theory, as some dielectrics are strained in one way, and others in the opposite, while, on Maxwell's theory, the strain should all be of one kind. The statement on p. 97, that the sparking distance increases very much more rapidly than the increase in the difference of potential between the electrodes, should have been limited to the case where the electrodes are pointed; it is not true when the dimensions of the electrodes are large compared with the sparking distance. The proof of the expression for the electromotive force due to induction, on p. 170, does not seem to us to be sound; and the method of measuring the coefficient of self-induction of a coil was really invented by Maxwell, and given by him in his paper on the "Dynamics of the Electric Field," though it is not in the "Electricity and Magnetism."

We must, in conclusion, congratulate the author on having written one of the best treatises on elementary physics which it has ever been our good fortune to read.

J. J. T.

THE ART OF PAPER-MAKING.

The Art of Paper-Making. By Alexander Watt. (London: Crosby Lockwood and Son, 1890.)

THE author of this work, in the preface, expresses his thanks to certain gentlemen who have been good enough to conduct him through their mills and explain to him the various operations performed therein. From this we gather that the author is not only not a practical paper-maker, but that, up to the time of writing the book, he had but a limited and general knowledge of the subject. These conclusions are amply justified by a perusal of the book. This want of practical knowledge can hardly be wondered at, as the writer is already an authority on such widely different subjects as soap-making, leather manufacture, electro-metallurgy, electro-deposition, &c.

On the other hand, there is evidence that on the whole the author has devoted some considerable time to the reading up of his subject, though in many cases he has not consulted the latest authorities. For example, in speaking of the properties of cellulose, he quotes the opinions expressed by Mr. Arnot in his Cantor Lectures for 1877, since which time several additions have been made to our knowledge. We should have preferred to see more space devoted to this branch of the subject, as on the proper understanding of the properties of cellulose the scientific manufacture of paper depends.

Some of the statements with regard to cellulose are inaccurate and misleading, as for example, that "hydrochloric acid converts it into a fine powder without altering its composition," and again, that "nitric acid forms substitution products of various degrees, according to the strength of acid employed." As a matter of fact, ordinary nitric acid does not form nitro-substitution products with cellulose.

Under the head of the "Recognition of Vegetable Fibres by the Microscope," esparto—perhaps the most important raw material used in this country—is not even mentioned. The author's descriptions of the various mechanical appliances used in paper-making are, with one or two exceptions, accurate and fairly complete. In describing the chemical processes involved, however, the author occasionally gets out of his depth. For instance, he recommends certain qualities of rags to be boiled with 30 per cent. of caustic soda. At first we thought this was a misprint for 3 per cent., but on referring to the source of the information, we found that the author had quoted correctly. Again, we are told that the neutralization of chlorine in pulp by hyposulphite, which the author says is sometimes called thiosulphite, is effected when the liquor ceases to redden litmus paper.

In giving directions for the sizing of paper, the author appears to have left out a number of decimal points. According to him 100 parts of pulp require 10–12 parts of rosin, and 20–30 parts of starch, and from 30–50 parts of kaolin. In the interest of the consumer it is satisfactory to know that such numbers are impossible.

In the chapter containing directions for the testing of alkalies, alum, &c., the following extraordinary statement occurs: "There are two principal methods of analyzing or assaying alkalies by means of the test acid—namely, volumetric, or by volume, and gravimetric, or by weight, in which a specific gravity bottle, capable of holding exactly 1000 grains of distilled water, is used."

Another instance of looseness of style occurs in the statement that "the proportion of caustic soda per cwt. of rags varies to the extent of from 5 to 10 per cent. of the former to each cwt. of the latter."

The general plan of the book also shows want of careful preparation; for example under the head of "Action of Acids on Cellulose," the author discusses the action of the strongly alkaline solution of cuprammonium.

In speaking of the origin of the wood-pulp process, the author champions the right of his father to be regarded as the pioneer. Similarly, with regard to electrolytic bleaching, we are told that the modern Hermite process, which has been successfully applied to the bleaching of paper pulp, is the outcome of an invention patented by his brother in 1851. It is perfectly true that in this patent the electrolysis of chlorides was claimed, but this in no way diminishes the credit due to those who have based on this principle a practical and successful manufacturing process.

OUR BOOK SHELF.

A Contribution to the Natural History of Scarlatina, derived from Observations on the London Epidemic of 1887–88. By D. Astley Gresswell, M.A., M.D. Oxon. (Oxford: Clarendon Press, 1890.)

THIS volume constitutes Dr. Gresswell's dissertation for the degree of Doctor of Medicine at Oxford, and is published "as a mark of distinction" by the University. It is the result of some six months clinical work at the South-Western Fever Hospital of the Metropolitan Asylums Board, and the author is to be congratulated alike upon the large number of carefully recorded observations which he has made, and upon the evidence his book affords of his careful study of the literature of scarlatina.

Between September 1887 and February 1888 Dr. Gresswell had charge of nearly 600 fever patients, and the statistical tables with which his treatise abounds are thus based on no inconsiderable number of cases. After some

general considerations with respect to the disease, certain special symptoms are passed in review, particular attention being devoted to their relation to season. Then follows an exhaustive discussion of scarlatinal albuminuria. Perhaps the most striking fact brought out in the book is the contrast presented in regard to this symptom between the patients admitted during October and November, and those admitted during December and January. While albumen was discovered previous to "getting up for the first time" in only rather more than 50 per cent. of the latter group of cases, it was found in every such case investigated in the two earlier months. This universal occurrence of albuminuria in the first three weeks of the disease, during the height of the epidemic, is eminently noteworthy; as Dr. Gresswell says, it could not have been "a mere casual incident of pyrexial origin," nor could he account for it by differences of sex, age, stage of illness on admission, or treatment. All observers of the scarlatina of the latter half of 1887 seem to have been impressed with the unusually frequent occurrence of albumen in the urine. Dr. Sweeting referred it to overcrowding; Dr. Gresswell inclines to consider it as accounted for by the change in the character of the disease during the progress of the epidemic.

Although the chapter on "postural albuminuria" is of considerable interest, much of its subject-matter is not immediately connected with the natural history of scarlatina, while an important question like secondary sore throat is very briefly dealt with. Two cases of "reversio eruptionis" are quoted, but in one, as Dr. Gresswell admits, there is but scant evidence that the child had scarlatina on admission.

Attention is particularly devoted throughout to the variations in the phenomena of the disease in their relation to season, and the concluding section of the work contains some interesting suggestions with regard to this topic. The author upholds the view that variations in the life-history of the micro-organism of scarlatina lie at the root of the matter, but surely he goes rather far afield when he alludes to the possibility of the "interfertilization of different kinds of microbes."

The hope may be entertained that Dr. Gresswell will not lack imitators in selecting this particular branch of study as the subject of dissertation for the M.D. degree. There is abundant scope for research at the Asylums Board hospitals, and if the work be as full of interest as it is in the example before us, it cannot fail to redound to the credit of the worker.

Le Soleil; les Étoiles. By Gabriel Dallet. (Paris: Firmin-Didot et Cie., 1890.)

THE chapters on the constellations, in this work, are of a very comprehensive character. That devoted to a description of instruments of observation contains a fair amount of useful information, whilst tables of parallaxes and proper motions, double and variable stars, and other interesting objects visible in our hemisphere, compiled from the British Association Catalogue, *Connaissance des Temps*, and *L'Annuaire du Bureau des Longitudes*, are plentifully and properly distributed throughout, and render the work what it purports to be, an "Astronomie Pratique." The author is, however, evidently not at home when writing on spectroscopy, and is considerably behind the recent developments in that branch of astronomy. As an example of this deficiency we would cite his assertion that the spectrum of the Orion nebula consists of three bright lines, as discovered by Dr. Huggins in 1864, although recent observations have increased the number visible to nine, and the photographic spectrum shows many times this amount.

The author seems also to have very vague ideas as to the origin of the universe. He says:—"Notre soleil et ses planètes ont dû se trouver au centre d'une nébuleuse, mais la matière cosmique qui la formait comprenait une variété considérable d'éléments chimiques qui ne se présentent pas dans nébuleuses proprement dites"; a conclusion which leads him to write:—"Nous pouvons dire avec M. Huggins que les nébuleuses à spectre gazeux sont des systèmes ayant une structure et une organisation à part, et qui sont d'un ordre différent de celui dont notre soleil, avec ses planètes, faisait partie dans la nébuleuse primitive"; although in justice to Dr. Huggins it should be said that he has now rejected the conviction that "the nebulæ which give a gaseous spectrum are systems possessing a structure, and a purpose in relation to the universe, altogether distinct and of another order from the great group of cosmical bodies to which our sun and the fixed stars belong."

Little spectroscopy other than this is included in the work, observations of sun-spots and prominences being mainly considered from a pictorial point of view. There is no doubt, however, that the twelve maps of the heavens will be of service to amateur astronomers, and that the ninety-three illustrations are in general well chosen. We should be glad, therefore, to see the slight inaccuracies that we have indicated eliminated in a future edition.

Father Perry, F.R.S. By Aloysius L. Cortie, S.J. (London: The Catholic Truth Society, 1890.)

THE author of this little book was a friend of the late Father Perry, and is, therefore, most capable of writing a sketch of his life and work, and few lives could afford more of the material which makes such a sketch interesting.

The programme of work undertaken by the deceased astronomer ten years ago at Stonyhurst College Observatory was comprehensive. It included the daily drawing of the sun when possible, the measurement of the depth of the chromosphere, the heights of prominences, and observations of sun-spot spectra, and this programme was faithfully adhered to up to the time of his death. The method of obtaining the drawings of sun-spots which have appeared in the Memoirs of the Royal Astronomical Society is described, and the reproduction of two of the largest spots shows how much can be effected by means of the pencil. These drawings are of great importance, and supplement solar photographs. The main object in making them was to throw light upon the theories of the mode of formation of spots, and to find, if possible, the clue to the connection between terrestrial magnetism and solar activity. This discussion however, was cut short by death.

A copy of the photograph of the solar corona, from the observation of which Father Perry was carried to his death-bed, testifies more than volumes of words to the character of the man whose life is before us, and the long list of published papers and the expeditions in which he took part speak of his industry. A few of his notes on faculae and veiled spots are appended, and render this volume of 112 pages something more than a biography.

Prodomus Faunæ Mediterraneæ sive Descriptio Animalium maris Mediterranei incolarum quam comparata silva rerum quatenus innotuit adjectis locis et nominibus vulgaribus eorumque auctoribus in commodum Zoologorum congessit Julius Victor Carus. Vol. I. Pars II., Vol. II., Pars I. (Stuttgart: E. Schweizerbart'sche Verlagshandlung.)

SOME five years ago we welcomed the appearance of the first part of Prof. J. Victor Carus's "Prodomus Faunæ Mediterraneæ" (NATURE, vol. xxxi. p. 201); since then, two additional parts have been published. The second completes vol. i., and contains the Arthropods; it was published early in 1885. The third part, the first of vol. ii., was published late in last year, and contains the Brachiostomata and Mollusca.

Beyond the record of the appearance of these parts, and the expression of our hope that the author will speedily hasten the completion of his work, the usefulness of which will be greatly increased thereby, we have nothing to add to our previous notice.

LETTERS TO THE EDITOR.

Spiny Plants in New Zealand.

IN Mr. Wallace's recent work on "Darwinism," reference is made to the absence of spiny and prickly plants in oceanic islands in disproof of Prof. Geddes's theory that spines are an indication of the ebbing vitality of a species. Mr. Hemsley's remarks on the subject are quoted, and an explanation of the occurrence of spines in our only species of *Rubus* and in *Aciphylla* is given. In regard to the former it is stated (p. 433, colonial edition):—"In New Zealand the prickly *Rubus* is a leafless trailing plant, and its prickles are probably a protection against the large snails of the country, several of which have shells from two to three and a half inches long." The explanation seems to me to be a very unsatisfactory one, and indeed to be quite incorrect. The snails referred to (*Placostylis bovinus, Paryphanta Busbyi*, and *P. Hochstetteri*) are very uncommon; I do not know that they occur at all in the South Island. The *Rubus*, on the other hand, is everywhere a most abundant and aggressive plant, springing up especially in bush clearings, whether made by fire or by the axe alone. It is also incorrect to speak of it as a *leafless* trailing plant. Sir Joseph Hooker, who is the first authority on the New Zealand flora, has united all the forms of *Rubus* found in these islands into one polymorphic species, and even the most inveterate species-makers have never yet successfully disputed his dictum. It must, however, be acknowledged that *four* if not *five* very distinct varieties are included under the common name of *Rubus australis*. Of these only the variety *cissoides* of the "Flora Novæ-Zealandiæ" is leafless, its leaves being reduced to prickly midribs. All the other forms are leafy, some densely so, and these are by far the most abundant.

The true explanation of the prickles is most probably that they serve as climbing organs. No doubt all the developments of the epidermis in the larger species of the genus *Rubus* served primarily for protection against grazing animals. This is evidently the case in the common raspberry. But even in the various forms of the European blackberry or bramble, the prickles seem to help the plants in their scrambling growth to overtop those shrubs among which they grow. This is very evidently the case with our New Zealand bramble, or "bush-lawyer," as it is suggestively termed. It is a plant which grows especially at the edges of the bush or in clearings, and it quickly climbs over the plants among which it lives. If we take hold of a petiole (the stems have no prickles) we find it provided on the under side with a line of strong prickles, all curved downwards so as to give them good holding power. Their catch is further improved by the sharp bend in a direction opposite to their curvature which the petiole and petiolules take. One has only to attempt to pull a "lawyer" down from the plant on which it is climbing to see that the snail-hypothesis is not the correct one.

Any explanation of the formidably spinous leaves of *Aciphylla* is at the best hypothetical. Perhaps the theory that they may have gained their spines to prevent them from being trodden down or eaten by the Moas, is as good as any other. In a paper on the origin of the New Zealand flora, published in vol. xiv. of the Transactions of the N.Z. Institute, I have made reference (p. 496) to the scarcity of spiny and prickly plants. It is there shown that in cases where such defensive modifications occur the plants are either wide-spread in their distribution, having probably, before spreading into these islands, acquired their characters in other regions where they were of service; or that they belong to genera having extensive distribution. I have also pointed out that in pungent-leaved plants, such as species of *Leucopogon, Archeria*, &c., the strictly endemic species have lost the pungent tips. The same remark holds as to the barbed spines of *Acæna*, which serve to distribute the seeds, probably by mammalian agency. Of the seven described species two have a wide distribution outside of these islands, and have strong barbs. Two endemic species have the barbs not so well developed, while in the other three species—also endemic—they are wanting altogether.

Can anyone offer any suggestion as to the formidable nature of the stinging-hairs of our common nettle—*Urtica ferox?* In *U. incisa* and *U. australis* the stinging-hairs are few in number and feeble in their urticating properties. But *U. ferox* is a species confined, as far as I know, to these islands, and it has developed a formidable array of large and very poisonous hairs. It is worthy of remark that though so strongly protected in one direction it is particularly liable to insect attacks, it being often very difficult to find a perfect leaf. I cannot suggest any adequate explanation. GEO. M. THOMSON.

Dunedin, N.Z., May 14.

Drowned Atolls.

AS Captain Wharton speaks of the Macclesfield Bank as the so-called "drowned atoll" of the China Seas, it may be interesting to note that in the recent survey of it there were found no less than 15 genera, including 27 species, of living corals growing in depths from 21 to 44 fathoms, the dredge at each haul always bringing up living specimens, and of these only four were found growing on the more shallow rim of the Tizard Bank. P. W. BASSETT-SMITH.

As my opinion is that all the submerged atolls are in vigorous growth, I concur, of course, in Mr. Bassett-Smith's view, in the paragraph above, that the term "drowned," as indicating "dead," is a misnomer; and I inserted the words "so-called" to express this. The examination of the Macclesfield and Tizard Banks strongly supports this view.

W. J. L. WHARTON.

The Essex Bagshots.

MR. H. W. MONCKTON has done good service in calling the attention of geologists to the section through Brentwood Common (NATURE, vol. xlii. p. 198); and I am glad to say that I entirely agree with the interpretation of the section which he has suggested. The classification of all these beds as "Lower Bagshot" is in fact but a repetition of the error committed in former years in the Newbury country (see *Q.J.G.S.*, vol. xliv. pp. 178, 179). Lithological and palæontological evidence now concur to prove what seemed to me in the highest degree probable when the discovery of fossils in the Bagshot Beds at Frierning was announced in the new edition of the "Geology of London" last year, and what I suggested on general grounds three years ago (see *Geological Magazine*, March 1887, p. 115); namely, that in the Essex area there is an attenuation of the lower sands implying a transgressive relation of the "Bagshots" to the London Clay, such as has been shown by me (*Q.J.G.S.*, vols. xliii. and xliv.) to occur along the northern margin of the Bagshot area from Englefield Green to Farley Hill, south of Reading. A. IRVING.

Wellington College, Berks, June 30.

A Remarkable Appearance in the Sky.

THE remarkable appearance in the sky noted by your correspondent in NATURE of June 26 (p. 198), as observed in Sussex, on night of 17th inst., was also well seen here. I enclose sketches which afford an approximate idea of the phenomenon as observed on both the 17th and 25th inst. The former was the first conspicuous occurrence here this season of those "luminous boreal night-clouds," of which sketches have been forwarded to NATURE by the writer for some years past, but from another locality of residence at a higher elevation. This may account for failure of earlier observation during the present year. The luminous forms have become less definite, the outlines being faint and nebulous, as contrasted with the bright and definite cirro-form cloudlets seen when first noted, at considerably higher altitudes above the northern horizon.

Kensington, June 28. D. J. ROWAN.

DARKEST AFRICA.[1]

IT would be out of place in these pages to discuss Mr. Stanley's remarkable narrative of a remarkable expedition so far as the main purpose of that expedition is concerned. It is nearly four years since the interest in the position and fate of Emin Pasha reached its height in this country. The pages of NATURE and the columns of the daily press of the time will afford evidence of the universality and intensity of that interest, and of the reality of the belief that Emin and his people were in imminent danger of being exterminated by the Mahdists. Mr. Stanley insists on the ideal of Emin's conduct and character which was universally accepted at the time, as those of a hero who, in the face of danger and at the risk of death, loyally clung to his post and remained faithful to his duty and the people who regarded him as their leader and chief. As a man who had during his twelve years' sojourn in the Equatorial provinces made large contributions to science, the scientific world was naturally interested in his safety. Substantial evidence of what Emin has done for science may be seen in our own Natural History Museum. To rescue and relieve the pioneer of science and of civilization was the one object of the Expedition with the leadership of which Mr. Stanley was entrusted. It is evident from his narrative that the object was ever before his eyes, and that all else was subordinate. Through dangers innumerable and sufferings that might have daunted all but the boldest and truest spirits, the purpose for which the Expedition was organized was accomplished. Emin and all of his people who cared to accompany him were rescued, and that just in time; for, according to the latest reports, the Mahdists are now swarming on the shores of Albert Nyanza. That Emin presented himself to Mr. Stanley in a light somewhat different from the ideal; that the Governor was reluctant to leave; that most of his people were disloyal and demoralized wretches who might have been left to the tender mercies of the Mahdi, with whom they could easily have made terms; that there were other features about the expedition that may leave room for criticism, do not affect the general result. Mr. Stanley has once more proved his supremacy as a man of action, as a leader whose single aim is to accomplish what he undertakes. Even were Emin as full of blemishes as he is represented in Mr. Stanley's narrative, no one need regret the Expedition sent to his relief; it has helped to keep alive the sentiments of chivalry and humanity in the midst of a civilization in danger of becoming too materialistic, and given opportunity for the exercise of those noble qualities which make us proud of our race.

The truth is that no two men could be more dissimilar in character and conduct than are Emin and Mr. Stanley. They seem quite incapable of understanding each other; the one has no sympathy with the other's pursuits. Stanley is, before everything, a man of action, who goes direct to the accomplishment of whatever purpose he undertakes; Emin is a student of Nature, a man of science, who, by force of circumstance, had become ruler of a province, and military leader. As a man of science he may be too much given to making allowances to be fitted for a post where quickness of decision and rapidity of action were necessary, and where he had to deal with people with whom force was the only remedy. Whatever may be his weaknesses, science at least cannot regret the rescue of one of her most devoted disciples. With all Mr. Stanley's apparent contempt for science and her students, he himself has been one of her most successful pioneers.

It is hard to say whence Mr. Stanley has obtained his notion of the character of scientific men; and we are not disposed to take his verdict too seriously, when we remember the circumstances under which his book was written, and the many irritating conditions to which he had without doubt been subjected by the conduct of Emin and his people. The most satisfactory feature about the passage in which he flouts at science and its votaries is its inconsistency. This and other passages in his book, in which Mr. Stanley deals with science, only show that he is not equally strong all round; that, notwithstanding the valuable contributions he has made to science in this and his previous writings, he himself is not largely endowed with the scientific spirit.

While we are disposed to be critical, may we refer to one or two other passages in Mr. Stanley's book which seem to us to show that he had not quite recovered that equanimity which was so bitterly tried, even down to the arrival at Bagamoyo? Speaking of the fine race of the Wahuma, he scoffs at "some philological *nidderings*" for classing them and many other tribes in Central and South Africa under the common name of *Bantu*, which, as he truly tells us, simply means men. If Mr. Stanley intends by this to protest against the implication that, because a variety of peoples speak a certain type of language, therefore they must all be of common descent, he is quite justified. But that the languages over a large area of Central and South Africa have all a certain family likeness there can be little doubt; and the term Bantu is quite as useful as any other to express this fact. Possibly Mr. Stanley might be able to suggest a better term. In his chapter on the tribes of the grass land, where the fine Wahuma race is dominant, Mr. Stanley has some most suggestive and interesting remarks on the various types of African peoples, and on the immigration which must have taken place at an early period from Asia into Africa. In its ethnology, as in so many other respects, this strange continent presents many puzzles for the student of science to solve. Mr. Stanley's recent journey was, to a large extent, through the borderland which forms a sort of meeting-ground for various types of peoples; and the contributions he has made to ethnology will cover a multitude of flouts at science and its votaries. The many interesting details he gives concerning the pigmies that pestered his column so much on its march through the forest form one of the most prominent features of his narrative. Prof. Flower has so recently (NATURE, vol. xxxviii. pp. 44 *et seq.*) fully discussed the whole subject of pigmy races, that we need only refer the reader to Mr. Stanley's pages in confirmation of Prof. Flower's views. In his own graphic and peculiar way, Mr. Stanley claims a high antiquity for these tiny folks; and in this he is supported by the evidence adduced by Prof. Flower. Mr. Stanley himself, on his greatest journey of all, heard of these pigmies about the great bend of the Congo; on his last journey he found the forest swarming with them. Outside the sunless gloom of the forest they pine and die. They are naturally timid, and continually on the offensive against all comers. But when treated kindly they become devoted to their benefactors, and serve them faithfully even to their own hurt. Full details of the various dimensions of these pigmies are given from Emin's notes (vol. ii. p. 150); but we may quote here what Mr. Stanley says about the first of these pigmies whom he had an opportunity of inspecting. A man and a woman were brought to him at the Avatiko plantation, on the Ituri. The man was apparently about 21. Mr. Bonny conscientiously measured him, with the following result:—

"Height, 4 ft.; round head, 20½ in.; from chin to back top of head, 24¼ in.; round chest, 25½ in.; round abdomen, 27¾ in.; round hips, 22½ in.; round wrist, 4½ in.; round muscle of left arm, 7½ in.; round ankle, 7 in.; round calf of leg, 7¾ in.; length of index finger, 2 in.; length of right hand, 4 in.; length of foot, 6¼ in.; length of leg, 22 in.; length of back, 18½ in.; arm to tip of finger, 19¾ in.

"This was the first full-grown man we had seen. His

[1] "In Darkest Africa: or the Quest, Rescue, and Retreat of Emin, Governor of Equatoria." By Henry M. Stanley. Two Vols. (London: Sampson Low and Co., 1890.)

colour was coppery; the fell over the body was almost furry, being nearly half an inch in length. His head-dress was a bonnet of a priestly form, decorated with a bunch of parrot feathers; it was either a gift or had been stolen. A broad strip of bark covered his nakedness. His hands were very delicate, and attracted attention by their unwashed appearance."

The chapter on the forest in the second volume, abounds with information concerning the various tribes which inhabit the forest region. There is a family likeness among all the varieties. With regard to the pigmies, Mr. Stanley maintains there are two distinct types (Batwa and Wambutti), which differ as much from each other as a Turk would from a Scandinavian. The Batwa have longish heads and long narrow faces, reddish small eyes, set close together, which give them a somewhat ferrety look, sour, anxious, and querulous. The Wambutti have round faces, gazelle-like eyes, set far apart, open foreheads, which give one an impression of undisguised frankness, and are of a rich, yellow, ivory complexion. The Wambutti occupy the southern half of the Ituri region, the Batwa the northern, and extend south-easterly to the Awamba forest on both banks of the Semliki river, and east of the Ituri. The women are agriculturists and the men hunters. Though their nomad habits are often annoying to the forest tribes of larger make, yet the latter find the pigmies exceedingly useful as scouts who give warning of the approach of the enemy. As might have been expected, the forest peoples are all of lighter complexion than the inhabitants of the open grass lands. With regard to the poison of the arrows of these pigmies, Mr. Stanley does not insist so strongly on its insect origin as he did in his letter to the Royal Geographical Society. The poison, he states, seems to be made from a species of arum. It is evident from these allusions that Mr. Stanley's contributions to a knowledge of the ethnology of the region are of great interest; indeed, they entitle him to be classed among those students of science whom he professes to despise.

The great forest, in which so much of the time of the Expedition was spent, and which entailed upon it so much suffering and so many losses, pervades the whole work; and one might even trace its depressing influences upon Mr. Stanley's style in the earlier chapters of the book. There are several points of great scientific interest connected with the forest. Mr. Stanley refers to Prof. Drummond in terms unnecessarily severe, because in his book on "Tropical Africa" he describes the type of African

Cascades of the Nepoko.

forest as quite different from that of Brazil. But Prof. Drummond can only be taken as referring to that part of Africa with which he is perfectly familiar, the Lake Nyassa region, where as in East Africa generally the "forest" is of the open park-like character, with dense patches here and there. But the fact is, we are apt to forget that Africa is a great continent covering some 11 million square miles, and that its surface presents a great variety of features. Here is how Mr. Stanley puts it:—

"Nyassaland is not Africa, but itself. Neither can we call the wilderness of Masai Land, or the scrub-covered deserts of Kalahari, or the rolling grass land of Usukuma, or the thin forests of Unyamwezi, or the ochreous acacia-covered area of Ugogo, anything but sections of a continent that boasts many zones. Africa is about three times greater than Europe in its extent, and is infinitely more varied. You have the desert of deserts in the Sahara, you have the steppes of Eastern Russia in Masai Land and parts of South Africa, you have the Castilian uplands in Unyamwezi, you have the best parts of France represented by Egypt, you have Switzerland in Ukonju and Toro, the Alps in Ruwenzori—you have Brazil in the Congo basin, the Amazon in the Congo River, and its immense forests rivalled by the Central African forest which I am about to describe.

"The greatest length of this forest, that is from near Kabambarré in South Manyuema to Bagbomo on the Welle-Makua in West Niam-niam, is 621 miles; its average breadth is 517 miles, which makes a compact square area of 321,057 square miles. This is exclusive of the forest areas separated or penetrated into by campo-like reaches of grass land, or of the broad belts of timber which fill the lower levels of each great river basin like the Lumani, Lulungu, Welle-Mubangi, and the parent river from Bolobo to the Loika River."

"The Congo and the Aruwimi Rivers enabled us to penetrate this vast area of primeval woods a considerable length. I only mean to treat, therefore, of that portion which extends from Yambuya in 25° 3½′ E. L. to Indesura, 29° 59′ = 326½ English miles in a straight line."

Mr. Stanley's description of an African tropical forest is also worth quoting:—

"Imagine the whole of France and the Iberian peninsula closely packed with trees varying from 20 to 180 feet high, whose crowns of foliage interlace and prevent any view of the sky and sun, and each tree from a few inches

to four feet in diameter. Then from tree to tree run cables from two inches to fifteen inches in diameter, up and down in loops and festoons and W's and badly-formed M's; fold them round the trees in great tight coils, until they have run up the entire height, like endless anacondas; let them flower and leaf luxuriantly, and mix up above with the foliage of the trees to hide the sun, then from the highest branches let fall the ends of the cables reaching near to the ground by hundreds with frayed extremities, for these represent the air roots of the Epiphytes; let slender cords hang down also in tassels with open thread-work at the ends. Work others through and through these as confusedly as possible, and pendent from branch to branch—with absolute disregard of material, and at every fork and on every horizontal branch plant cabbage-like lichens of the largest kind, and broad spear-leaved plants—these would represent the elephant-eared plant—and orchids and clusters of vegetable marvels, and a drapery of delicate ferns which abound. Now cover tree, branch, twig, and creeper with a thick moss like a green fur. Where the forest is compact as described above, we may not do more than cover the ground closely with a thick crop of phrynia, and amoma, and dwarf bush; but if the lightning, as frequently happens, has severed the crown of a proud tree, and let in the sunlight, or split a giant down to its roots, or scorched it dead, or a tornado has been uprooting a few trees, then the race for air and light has caused a multitude of baby trees to rush upward—crowded, crushing, and treading upon and strangling one another, until the whole is one impervious bush.

"But the average forest is a mixture of these scenes. There will probably be groups of fifty trees standing like columns of a cathedral, grey and solemn in the twilight, and in the midst there will be a naked and gaunt patriarch, bleached white, and around it will have grown a young community, each young tree clambering upward to become heir to the area of light and sunshine once occupied by the sire. The law of primogeniture reigns here also."

What is the real extent of the continuous forest area? Is the forest of Mr. Du Chaillu in the Ogowé region, and that in which Livingstone wandered between Tanganyika and Nyangwé, really part of the same great forest through which the Ituri flows? The two slave-raiding parties which Mr. Stanley met on the Ituri, and which had come

View of the South End of Albert Nyanza.

north from Kibongé on the Upper Congo, journeyed through dense forest the whole way, meeting with not a patch of open grass. That the forest may be almost continuous from about Nyangwé to the Ituri, and for some distance northwards, is probable enough. But that there is one continuous forest from the Lower Ogowé to the plateau above Lake Albert is highly improbable. Indeed, from the observations of De Brazza and of Mr. Stanley himself on the Lower Congo, and in the country between that and the Ogowé, we know that there does exist much open country there. Even in the region with which Mr. Stanley specially deals—the region along the Ituri and to the north and south—it must be remembered that it has been traversed only along one or two lines. Considering the close network of rivers which characterize the region, it is probable enough that over a very great area we have one dense forest. Readers of Schweinfurth, Emin, and Junker, will remember the "gallery" forests which they describe to the north and north-east of Mr. Stanley's route; forests lining the banks of the rivers, and stretching for several miles from their banks. It may be, then, that in the Ituri region, with its many rivers, we have a series of gallery forests which have coalesced or overlapped into one continuous forest. With the rapidly progressing opening-up of Africa, this is a problem that cannot remain long unsolved. At the same time it should be remembered that even in the Amazonian basin the forest is by no means continuous, but gives way in many places to great stretches of open land.

Mr. Stanley was here in what is probably the rainiest region of all Africa. We were at first disposed to believe that most of the moisture found its way westwards from the Indian Ocean. But this is a point on which Mr. Stanley made many careful observations, and his conclusion that the great rain-bearing winds come from the Atlantic must meantime be accepted. At the same time it is to be hoped that the Government of the Congo Free State will establish a series of observing-stations over as wide an area as possible, and so collect data which will be useful not only to science, but of service to its own economic interests. One great service rendered by Emin Pasha was the daily series of observations which he carried on at Lado for several years, and which render that station the one place in Central Africa for which we have trustworthy meteorological data. Emin carried on his observations during the whole period he was with Mr. Stanley,

down to Bagamoyo, and it is to be hoped that these will one day be given to the world.

About the prevailing plateau character of the whole country traversed by Mr. Stanley there can be no doubt. Some of its remarkable features are well brought out in many of the fine illustrations which adorn the book. The importance of this feature in the opening up of the centre of the continent under the guidance of Europeans is evident. The magnificent grassy plateau between Lake Albert and the edge of the forest, where the Expedition lived many weeks while waiting for Emin and his people, seems really a fine country from this point of view. What could be accomplished by partially clearing the forest may be seen from the planting operations at Fort Bodo, where Lieutenant Stairs and Dr. Parke lived for many months, and where they grew large crops of maize, bananas, tobacco, and other cultures. Here is a description of the country as seen from the plateau above Lake Albert:—

"Yesterday Jephson and I had examined the summits of the hills, and in one of the hollows we had discovered tree ferns, standing eight feet high, with stalks eight inches in diameter. We also brought with us a few purple flowering heliotropes, aloes, and rock ferns for the Pasha. All this has inspired him with a desire to investigate the flora for himself.

"These hills have an altitude varying from 5400 to 5600 feet above the sea. The folds and hollows between these hills are here and there somewhat picturesque, though on account of the late grass burnings they are not at their best just now. Each of the hollows has its own clear water rillet, and along their courses are bamboos, tree ferns, small palms, and bush, much of which is in flower. From the lively singing of the birds I heard yesterday, it was thought likely this insatiable collector might be able to add to his store of stuffed giant-larks, thrushes, bee-eaters, sun-birds, large pigeons, &c. Only four specimens were obtained, and the Pasha is not happy.

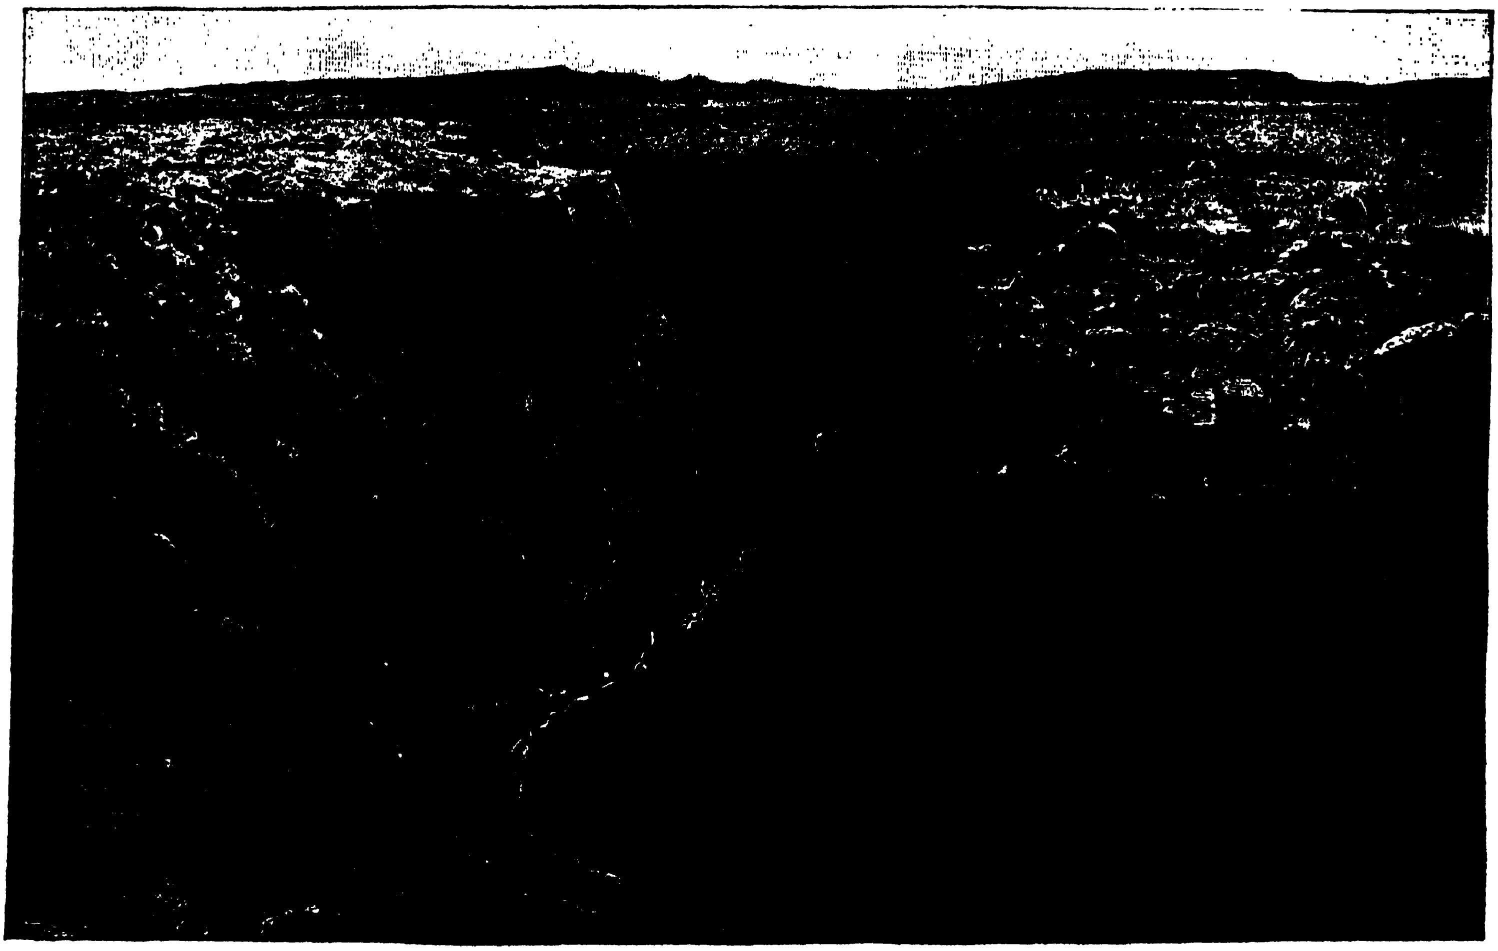
Ruwenzori: from Karimi. (From a Photograph.)

"In a bowl-like basin, rimmed around by rugged and bare rocks, I saw a level terrace a mile and a half long by a mile wide, green as a tennis lawn. Round about the foot of this terrace ran a clear rivulet, through a thick bank of woods, the tops of which just came to the level of the terrace. It has been the nicest site for a mission or a community of white men that I have seen for a long time. The altitude was 5500 feet above the sea. From the crest of the rocky hills encircling it we may obtain a view covering 3000 square miles of one of the most gloriously beautiful lands in the world. Pisgah, sixty miles westward, dominates all eminences and ridges in the direction of the forest world; Ruwenzori, 18,000 to 19,000, white with perpetual snow, eighty miles off, bounds the view south; to the east the eye looks far over the country of Unyoro; and north-east lies the length of the Albert Nyanza."

The instructive map prepared by Stanford from Mr. Stanley's observations affords an excellent idea of the physical features of the region traversed, and especially of the new features to the south of Lake Albert. This is even more strikingly brought out in the bird's-eye view of the region presented in one of the plates. The sudden fall from the plateau down to the level of Lake Albert, over 2000 feet, is remarkable. It is not quite so marked on the southern lake, which is not so much of the nature of a ravine; it may be because the lake has much diminished in size. That both lakes have greatly shrunk is evident; but that they ever formed one lake is a point

that can only be established by a series of careful observations. The same may be said as to the real nature of the change of level; is it permanent, or is it only of the nature of an oscillation of level, as is the case with other African lakes? What, again, are the forces which have been at work to produce these lake-chasms, and raise the magnificent mountain-mass of Ruwenzori? It may well be that the same forces have been at the bottom of both features, though possibly not in the precise fashion that Mr. Stanley would seem to indicate. There is here, evidently, a splendid field for geological research, and science has therefore every reason to wish that all this region may soon be restored to civilizing influences—included, if possible, within the sphere of the British East African Company. The volcanic mountain-mass of Ruwenzori, with its many snow-covered peaks and deeply scored sides, really covers a considerable area, with outlying peaks, like Gordon Bennett and Mackinnon, east and north-east. Both it and Lake Albert Edward are surrounded by a range or escarpment, 5500 to 6500 feet high. Stretching all the way south-east almost to the borders of Lake Victoria Nyanza, the table-land is much cut up by ravines, sometimes assuming a cañon-like shape, and marked here and there with peaks like Mfumbiro, 10,000 feet. On the Semliki itself, which joins Lakes Albert and Albert Edward, we find a forest, very similar to that on the Ituri, stretching some little distance up the lower slopes of Ruwenzori. The following description of the Semliki forest is worth quoting:—

"About a mile from Mtarega the grassy strip to which we had clung in preference was ended, the forest had marched across the breadth of the Semliki Valley, and had absorbed the Ruwenzori slopes to a height of seven thousand feet above us, and whether we would or no, we



Expedition winding up the Gorge o. Karya-muhoro.

had to enter the doleful shades again. But then the perfection of a tropical forest was around us. It even eclipsed the Ituri Valley in the variety of plants and general sappiness. There were clumps of palms, there were giant tree-ferns, there were wild bananas, and tall, stately trees all coated with thick green moss from top to root, impenetrable thickets of broad-leafed plants, and beads of moisture everywhere, besides tiny rillets oozing out every few yards from under the matted tangle of vivid green and bedewed undergrowth. It was the best specimen of a tropical conservatory I had ever seen. It could not be excelled if art had lent its aid to improve nature. In every tree-fork and along the great horizontal branches grew the loveliest ferns and lichens; the elephant-ear by the dozen, the orchids in close fellowship, and the bright green moss had formed soft circular cushions about them, and on almost every fibre there trembled a clear water-drop, and everything was bathed by a most humid atmosphere. The reason of all this was not far to seek; there were three hot-water springs, the temperature of which was 102°. This tract of forest was also in the cosiest fold of the snow mountains, and whatever heat a hot sun furnished on this place was long retained."

Mr. Stanley may be said in this expedition to have put the final touch to the definite delimitation of the Congo and the Nile basins. It looks only a few steps from the sources of the Ituri and its feeders, which go to swell the Congo, to the edge of the escarpment whose feet are lapped by the waters of Lake Albert, which sends its tribute to the Nile. That the Southern Muta Nzige (Lake Albert Edward) belongs to the Nile and not to the Congo system is finally proved. Mr. Stanley, who seems to have been still in a fighting mood while he was writing his book at Cairo, severely castigates the

map-makers for ignoring the work of the cartographers of ancient times. We need not quarrel with his manner of opening up a subject of great interest. What were the relations of Egypt, and therefore of ancient Europe, with Central Africa? It is certainly a noteworthy fact that, even in the oldest maps (whatever was the real nature of these maps), we find the Nile coming out of two lakes, and we find a range of mountains somewhere in the neighbourhood, called the Mountains of the Moon. It is not to be supposed that the people of Africa were less restless in ancient times than they are now, nor that the Egyptians did not make efforts to find out where their great river came from. Expeditions into the heart of Africa we read of in Herodotus and elsewhere. However the knowledge came—probably obtained through traders or from natives brought down as slaves to Egypt—there can be no doubt that the Ptolemaic maps of Africa bear some distant resemblance to reality. But all became much exaggerated as time went on. The maps of Africa became overcrowded with features the authority for which it was impossible to find out; the "Mountains of the Moon" stretched themselves right across the continent. That snowy Ruwenzori, Kilimanjaro, and Kenia formed the original nucleus out of which these mountains were evolved there can be little doubt. But modern discoveries have proved how unlike the maps of Africa, before d'Anville swept them clean, were to the reality, and how essential it was to make a new start. No one has done more than Mr. Stanley himself to fill the map of Africa with authentic features.

Mr. Stanley's pages teem with facts and suggestions of interest to science; we have only touched upon a few of the more prominent topics referred to in the work. Here, for example, are some curious data with regard to the distribution of malaria:—

South-west Extremity of Lake Victoria Nyanza.

"On the plateau of Kavalli and Undussuma, Messrs. Jephson, Parke, and myself were successively prostrated by fever, and the average level of the land was over 4500 feet above the sea.

"On descending to the Nyanza plain, 2500 feet lower, we were again laid up with fierce attacks.

"At Banana Point, which is at sea-level, ague is only too common.

"At Boma, 80 feet higher, the ague is more common still.

"At Vivi, there were more cases than elsewhere, and the station was about 250 feet higher than Boma, and not a swamp was near it.

"At Stanley Pool, about 1100 feet above sea-level, fever of a pernicious form was prevalent.

"While ascending the Congo with the wind astern we were unusually exempted from ague.

"But descending the Upper Congo, facing the wind, we were smitten with most severe forms of it.

"While ascending the Aruwimi we seldom thought of African fever, but descending it in canoes, meeting the wind currents, and carried towards it by river-flow and paddle, we were speedily made aware that acclimatization is slow.

"Therefore it is proved that from 0 to 5000 feet above the sea there is no immunity from fever and ague; that over forty miles of lake water between a camp and the other shore are no positive protection; that a thousand miles of river course may serve as a flue to convey

malaria in a concentrated form; that if there is a thick screen of primeval forest or a grove of plantains between the dwelling-place and a large clearing or open country there is only danger of the local malaria around the dwelling, which might be rendered harmless by the slightest attention to the system; but in the open country neither a house nor a tent is sufficient protection, since the air enters by the doors of the house, and under the flaps, and through the ventilators to poison the inmates.

"Hence we may infer that trees, tall shrubbery, a high wall or close screen interposed between the dwelling-place and the wind currents will mitigate their malarial influence, and the inmate will only be subjected to local exhalations.

"Emin Pasha informed me that he always took a mosquito curtain with him, as he believed that it was an excellent protector against miasmatic exhalations of the night.

"Question, might not a respirator attached to a veil, or face screen of muslin, assist in mitigating malarious effects when the traveller finds himself in open regions?"

As a matter of fact, we believe a veil or a mosquito curtain is found a useful preventive in malarial regions.

Mr. Stanley gives some natural history notes which he obtained from Emin. Here, for example, is a statement which he gives in Emin's own words, but which notwithstanding is somewhat astounding:—

"The forest of Msongwa is infested with a large tribe of chimpanzees. In summer-time, at night, they frequently visit the plantations of Mswa Station to steal the fruit. But what is remarkable about this is the fact that they use torches to light the way! Had I not witnessed this extraordinary spectacle personally, I should never have credited that any of the Simians understood the art of making fire.

"One of these same chimpanzees stole a native drum from the station, and went away pounding merrily on it. They evidently delight in that drum, for I have frequently heard them rattling away at it in the silence of the night."

The importance of this fact with regard to fire-using (it is not stated that they are fire-making) chimpanzees need not be pointed out. We cannot doubt the accuracy of Mr. Stanley's report, nor the trustworthiness of Emin's observation; but we should like to have more details.

Great expectations have been formed of Mr. Stanley's narrative of one of the most remarkable African expeditions on record. These expectations have not been disappointed. The reader who merely seeks for the excitement of adventure will find what he seeks in almost every page. We have written enough to prove that the student of science and the geographer will find the narrative teeming with novel and suggestive facts. There are no doubt a few marks of haste and fatigue on the part of the author; but the work is altogether worthy of Mr. Stanley's brilliant record, and entitles him, let us once more say, to be ranked among the foremost pioneers of science in "Darkest Africa."

By the courtesy of Messrs. Sampson Low and Co. we are able to give a few specimens of the 150 illustrations which add so much to the beauty and value of the book, which from the point of view of get-up is entirely creditable to all concerned. J. S. K.

PROBLEMS IN THE PHYSICS OF AN ELECTRIC LAMP.[1]

II.

At this stage it will perhaps be most convenient to outline briefly the beginnings of a theory proposed to reconcile these facts, and leave you to judge how far the subsequent experiments confirm this hypothesis. The theory very briefly is as follows:—From all parts of the incandescent carbon loop, but chiefly from the negative leg, carbon molecules are being projected which carry with them, or are charged with, negative electricity. I will in a few moments make a suggestion to you which may point to a possible hypothesis on the manner in which the molecules acquire this negative charge. Supposing this, however, to be the case, and that the bulb is filled with these negatively-charged molecules, what would be the result of introducing into their midst a conductor such as this middle metal plate which is charged positively? Obviously, they would all be attracted to it and discharge against it. Suppose the positive charge of this conductor to be continually renewed, and the negatively-charged molecules continually supplied, which conditions can be obtained by connecting the middle plate to the positive electrode of the lamp, the obvious result will be to produce a current of electricity flowing through the wire or galvanometer, by means of which this middle plate is connected to the positive electrode of the lamp. If, however, the middle plate is connected to the negative electrode of the lamp, the negatively-charged molecules can give up no charge to it, and produce no current in the interpolated galvanometer. We see that on this assumption the effect must necessarily be diminished by any arrangement which prevents these negatively-charged molecules from being shot off the negative leg or from

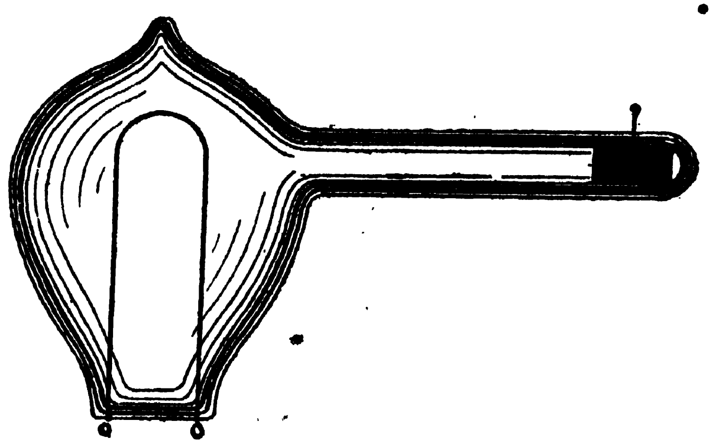


FIG. 8.—Collecting plate placed at end of a tube, 18 inches in length, opening out of the bulb.

striking against the middle plate. Another obvious corollary from this theory is that the "Edison effect" should be annihilated if the metal collecting plate is placed at a distance from the negative leg much greater than the mean free path of the molecules.

Here are some experiments which confirm this deduction. In this bulb (Fig. 8) the metal collecting plate, which is to be connected through the galvanometer with the positive terminal of the lamp, is placed at the end of a long tube opening out of and forming part of the bulb. We find the "Edison effect" is entirely absent, and that the galvanometer current is zero. We have, as it were, placed our target at such a distance that the longest range molecular bullets cannot hit it, or, at least, but very few of them do so. Here again is a lamp in which the plate is placed at the extremity of a tube opening out of the bulb, but bent at right angles (Fig. 9). We find in this case, as first discovered by Mr. Preece, that there is no "Edison effect." Our molecular marksman cannot shoot round a corner. None of the negatively charged molecules can reach the plate, although that plate is placed at a distance not greater than would suffice to produce the effect if the bend were straightened out. Following out our hypothesis into its consequences would lead us to conclude that the material of which the plate is made is without influence on the result, and this is found to be the case. Many of the foregoing facts were established

[1] Friday Evening Discourse delivered at the Royal Institution by Prof. J. A. Fleming, M.A., D.Sc., on February 14, 1890. Continued from p. 201.

by Mr. Preece as far back as 1885, and I have myself abundantly confirmed his results.

We should expect also to find that the larger we make our plate, and the nearer we bring it to the negative leg of the carbon, the greater will be the current produced in a circuit connecting this plate to the positive terminal of the lamp. I have before me a lamp with a large plate placed very near the negative leg of the carbon of a lamp, and we find that we can collect enough current from these molecular charges to work a telegraph relay and ring an electric bell. The current which is now working this relay is made up of the charges collected by the plate from the negatively charged carbon molecules which are projected against it from the negative leg, across the highly perfect vacuum. I have tried experiments with lamps in which the collecting plate is placed in all kinds of positions, and has various forms, some of which are here, and are represented in the diagrams before you; but the results may all be summed up by saying that the greatest effects are produced when the collecting plate is as near as possible to the base of the negative end of the loops, and, as far as possible, incloses, without touching, the carbon conductor. Time will not permit me to make more than a passing reference to the fact that the magnitude of the current flowing through the galvanometer when connected between the middle plate and the positive terminal of the lamp often "jumps" from a low to a high value, or *vice versâ*, in a remarkable manner, and

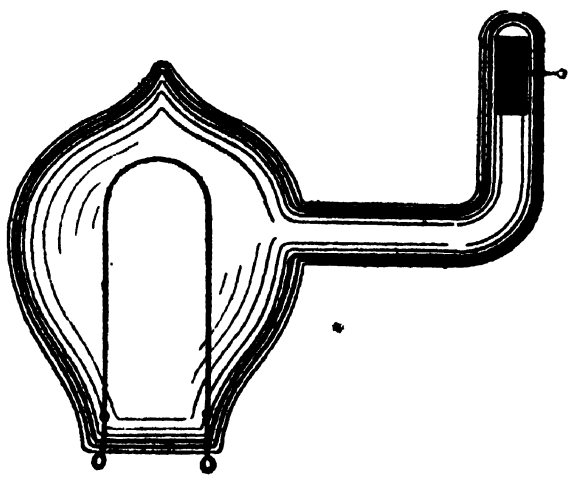

Fig. 9.—Collecting plate placed at end of an elbow tube opening out of the bulb.

that this sudden change in the current can be produced by bringing strong magnets near the outside of the bulb.

Let us now follow out into some other consequences this hypothesis that the interior of the bulb of a glow-lamp when in action is populated by flying crowds of carbon atoms all carrying a negative charge of electricity. Suppose we connect our middle collecting plate with some external reservoir of electric energy, such as a Leyden jar, or with a condenser equivalent in capacity to many hundreds of Leyden jars, and let the side of the condenser which is charged positively be first placed in connection through a galvanometer with the middle plate (see Fig. 10), whilst the negative side is placed in connection with the earth. Here is a condenser of two microfarads capacity so charged and connected. Note what happens when I complete the circuit and illuminate the lamp by passing the current through its filament. The condenser is at once discharged. If, however, we repeat the same experiment with the sole difference that the negatively charged side of the condenser is in connection with the middle plate then there is no discharge. The experimental results may be regarded from another point of view. In order that the condenser may be discharged as in the first case, it is essential that the negatively charged side of the condenser shall be in connection with some part of the circuit of the incandescent carbon loop. This experiment with the condenser discharged by the lamp may be then looked upon as an arrangement in which the plates of a charged condenser are connected respectively to an incandescent carbon loop and to a cool metal plate, both being inclosed in a highly vacuous space, and it appears that when the incandescent conductor is the negative electrode of this arrangement the discharge takes place, but not when the cooler metal plate is the negative electrode of the charged condenser. The negative charge of the condenser can be carried across the

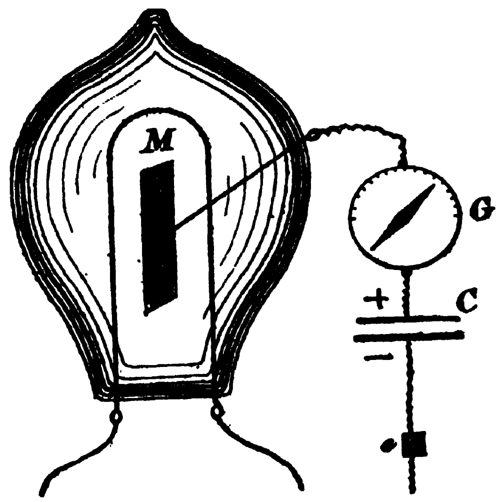

Fig. 10.—Charged condenser C discharged by middle plate M, when the positively charged side of condenser is in connection with the plate and other side to earth *e*.

vacuous space from the hot carbon to the colder metal plate, but not in the reverse direction.

This experimental result led me to examine the condition of the vacuous space between the middle metal plate and the negative leg of the carbon loop in the case of the lamp employed in our first experiment. Let us return for a moment to that lamp. I join the galvanometer between the middle plate and the negative terminal of the lamp, and find, as before, no indication of a current. The metal plate and the negative terminal of the lamp

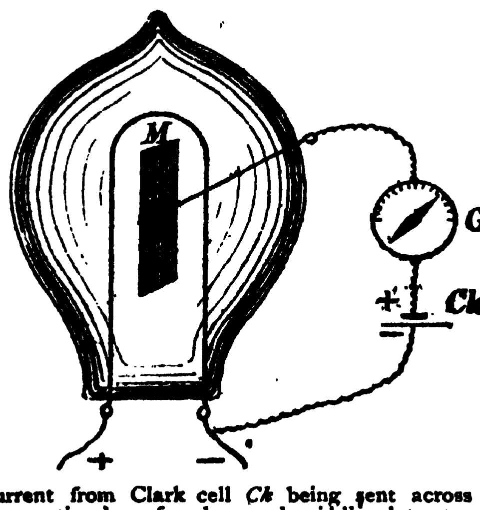

Fig. 11.—Current from Clark cell *Ck* being sent across vacuous space between negative leg of carbon and middle plate M. Positive pole of cell in connection with plate M through galvanometer G.

are at the same electrical potential. In the circuit of the galvanometer we will insert a single galvanic cell having an electromotive force of rather over one volt. In the first place let that cell be so inserted that its negative pole is in connection with the middle plate, and its positive pole in connection through the galvanometer with the negative terminal of the lamp (see Fig. 11). Regarding the circuit of that cell alone, we find that it consists of the cell itself, the galvanometer wire, and that half-inch of highly vacuous space between the hot carbon conductor

and the middle plate. In that circuit the cell cannot send any sensible current at all, as it is at the present moment connected up. But if we reverse the direction of the cell so that its positive pole is in connection with the middle plate, the galvanometer at once gives indications of a very sensible current. This highly vacuous space, lying between the middle metal plate on the one hand, and the incandescent carbon on the other, possesses a kind of unilateral conductivity, in that it will allow the current from a single galvanic cell to pass one way but not the other. It is a very old and familiar fact that in order to send a current from a battery through a highly rarefied gas by means of metal electrodes, the electromotive force of the battery must exceed a certain value. Here, however, we have indication that if the negative electrode by which that current seeks to enter the vacuous space is made incandescent the current will pass at a very much lower electromotive force than if the electrode is not so heated.

A little consideration of the foregoing experiments led to the conclusion that in the original experiment, as devised by Mr. Edison, if we could by any means render the middle plate very hot, we should get a current flowing through a galvanometer when it is connected between the middle plate and the negative electrode of the carbon. This experiment can be tried in the manner now to be shown. Here is a bulb (Fig. 12) having in it two carbon

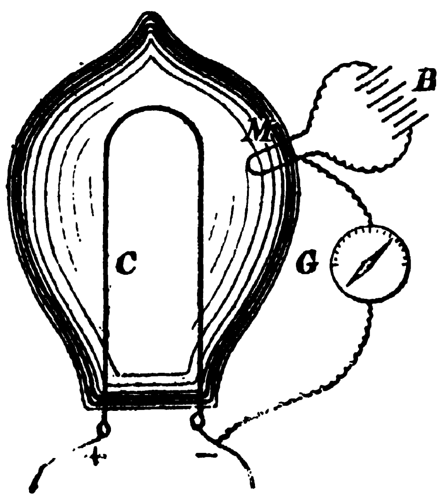

FIG. 12.—Experiment showing that when the "middle plate" is a carbon loop rendered incandescent by insulated battery B, a current of negative electricity flows from M to the positive leg of main carbon C across the vacuum.

loops; one of these is of ordinary size, and will be rendered incandescent by the current from the mains. The other loop is very small, and will be heated by a well-insulated secondary battery. This smaller incandescent loop shall be employed just as if it were a middle metal plate. It is, in fact, simply an incandescent middle conductor. On repeating the typical experiment with this arrangement, we find that the galvanometer indicates a current when connected between the middle loop and either the positive *or* the negative terminal of the main carbon. I have little doubt but that if we could render the platinum plate in our first-used lamp incandescent by concentrating on it from outside a powerful beam of radiant heat we should get the same result.

A similar set of results can be arrived at by experiments with a bulb constructed like an ordinary vacuum tube, and having small carbon loops at each end instead of the usual platinum or aluminium wires. Such a tube is now before you (see Fig. 13), and will not allow the current from a few cells of a secondary battery to pass through it when the carbon loops are cold. If, however, by means of well-insulated secondary batteries we render both of the carbon loop electrodes highly incandescent, a single cell of a battery is sufficient to pass a very considerable current across that vacuous space, provided the resistance of the rest of the circuit is not large. We may embrace the foregoing facts by saying that if the electrodes, but especially the negative electrode, which form the means of ingress and egress of a current into a vacuous space are capable of being rendered highly incandescent, and if at that high temperature they are made to differ in electrical potential by the application of a very small electromotive force, we may get under these circumstances a very sensible current through the rarefied gas. If the electrodes are cold a very much higher electromotive force will be necessary to begin the discharge or current through the space. These facts have been made the subject of elaborate investigation by Hittorf and Goldstein, and more recently by Elster and Geitel. It is to Hittorf that I believe we are indebted for the discovery of the fact that by heating the negative electrode we greatly reduce the apparent resistance of a vacuum.

Permit me now to pave the way by some other experiments for a little more detailed outline of the manner in which I shall venture to suggest these negative molecular charges are bestowed. This is really the important matter to examine. In seeking for some probable explanation of the manner in which these wandering molecules of carbon in the glow-lamp bulb obtain their negative charges, I fall back for assistance upon some facts discovered by the late Prof. Guthrie. He showed some years ago new experiments on the relative powers of incandescent bodies for retaining positive and negative charges. One of the facts he brought forward[1] was that

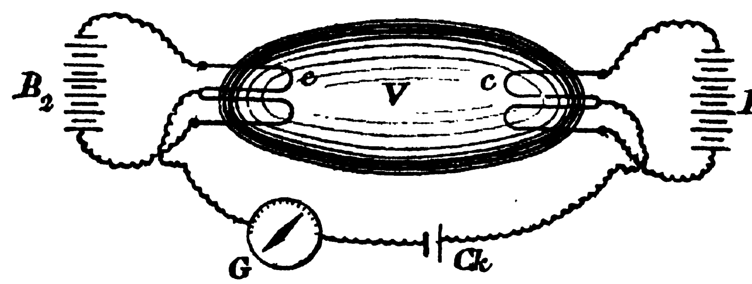

FIG. 13.—Vacuum tube having carbon loop electrodes, *c c*, at each end rendered incandescent by insulated batteries, B1, B2, showing current from Clark cell, *Ck*, passing through the high vacuum when the electrodes are incandescent.

a bright red-hot iron ball, well insulated, could be charged negatively, but could not retain for an instant a positive charge. He showed this fact in a way which it is very easy to repeat as a lecture experiment. Here is a gold-leaf electroscope, to which we will impart a positive charge of electricity, and project the image of its divergent leaves on the screen. A poker, the tip of which has been made brightly red-hot, is placed so that its incandescent end is about an inch from the knob of the electroscope. No discharge takes place. Discharging the electroscope with my finger, I give it a small charge of negative electricity, and replace the poker in the same position. The gold leaves instantly collapse. Bear in mind that the extremity of the poker, when brought in contiguity to the knob of the charged electroscope, becomes charged by induction with a charge of the opposite sign to that of the charge of the electroscope, and you will at once see that this experiment confirms Prof. Guthrie's statement, for the negatively charged electroscope induces a positive charge on the incandescent iron, and this charge cannot be retained. If the induced charge on the poker is a negative charge, it is retained, and hence the positively charged electroscope is not discharged, but the negatively charged electroscope at once loses its charge. Pass in imagination from iron balls to carbon molecules. We may ask whether it is a legitimate assumption to suppose the same fact to hold good for them, and that a hot

[1] "On a New Relation between Electricity and Heat," *Phil. Mag.*, vol. xlv. p. 308 (1873).

carbon molecule or small carbon mass just detached from an incandescent surface behaves in the same way and has a greater grip for negative than for positive charge? If this can possibly be assumed, we can complete our hypothesis as follows:—Consider a carbon molecule or small collection of molecules just set free by the high temperature from the negative leg of the incandescent carbon horseshoe. This small carbon mass finds itself in the electrostatic field between the branches of the incandescent carbon conductor (see Fig. 14). It is acted upon inductively, and if it behaves like the hot iron ball in Prof. Guthrie's experiment it loses its positive charge. The molecule then being charged negatively is repelled along the lines of electric force against the positive leg.

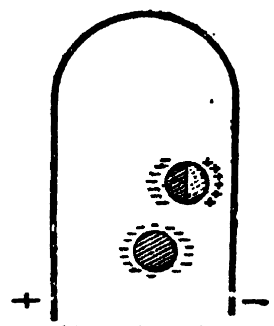

FIG. 14.—Rough diagram illustrating a theory of the manner in which projected carbon molecules may acquire a negative charge.

The forces moving it are electric forces, and the repetition of this action would cause a torrent of negatively-charged molecules to pour across from the negative to the positive side of the carbon horseshoe. If we place a metal plate in their path, which is in conducting connection with the positive electrode of the lamp carbon, the negatively charged molecules will discharge themselves against it. A plate so placed may catch more or less of this stream of charged molecules which pour across between the heels of the carbon loop. There are many extraordinary facts, which as yet I have been able only imperfectly to explore, which relate to the sudden changes in the direction of the principal stream of these charged molecules, and to their

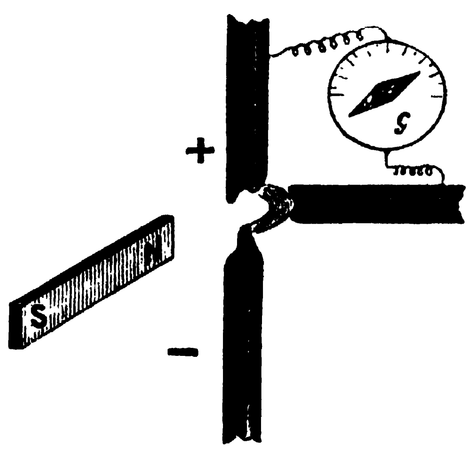

FIG. 15.—Electric arc projected by magnet against a third carbon, and showing a strong electric current flowing through a galvanometer, G, connected between the positive and this third carbon.

guidance under the influence of magnetic forces. The above rough sketch of a theory must be taken for no more than it is worth, viz. as a working hypothesis to suggest further experiments.

These experiments with incandescence lamps have prepared the way for me to exhibit to you some curious facts with respect to the electric arc, and which are analogous to those which we have passed in review. If a good electric arc is formed in the usual way, and if a third insulated carbon held at right angles to the other two is placed so that its tip just dips into the arc (see Fig. 15), we can show a similar series of experiments. It is rather more under control if we cause the arc to be projected against the third carbon by means of a magnet. I have now formed on the screen an image of the carbon poles and the arc between them, in the usual way. Placing a magnet at the back of the arc, I cause the flame of the arc to be deflected laterally and to blow against a third insulated carbon held in it. There are three insulated wires attached respectively to the positive and to the negative carbons of the arc, and to the third or insulated carbon, the end of which dips into the flame of the arc projected by the magnet. On starting the arc this third carbon is instantly brought down to the same electrical potential as the negative carbon of the arc, and if I connect this galvanometer in between the negative carbon and the third or insulated carbon, I get, as you see, no indication of a current. Let me, however, change the connections and insert the circuit of my galvanometer in between the positive carbon of the arc and the middle carbon, and we find evidence, by the violent impulse given to the galvanometer, that there is a strong current flowing through it. The direction of this current is equivalent to a flow of negative electricity from the middle carbon through the galvanometer to the positive carbon of the arc. We have here, then, the "Edison effect" repeated with the electric arc. So strong is the current flowing in a circuit connecting the middle carbon with the positive carbon that I can, as you see, ring an electric bell and light a small incandescent lamp when these electric-current

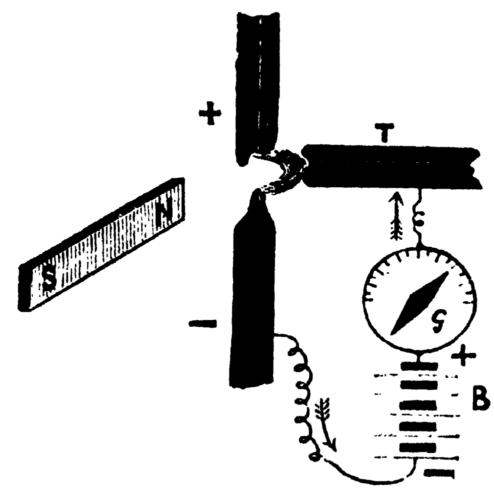

FIG. 16.—Galvanometer G and battery B inserted in series between negative carbon of electric arc and a third carbon to show unilateral conductivity of the arc between the negative and third carbons.

detectors are placed in connection with the positive and middle carbons.

We also find that the flame-like projection of the arc between the negative carbon possesses a unilateral conductivity. I join this small secondary battery of fifteen cells in series with the galvanometer, and connect the two between the middle carbon and the negative carbon of the arc. Just as in the analogous experiment with the incandescent lamp, we find we can send negative electricity along the flame of the arc one way but not the other. The secondary battery causes the galvanometer to indicate a current flowing through it when its negative pole is in connection with the negative carbon of the arc (see Fig. 16), but not when its positive pole is in connection with the negative carbon. On examining the third or middle carbon after it has been employed in this way for some time, we find that its extremity is cratered out and converted into graphite, just as if it had been employed as the positive carbon in forming an electric arc.

Time forbids me to indulge in any but the briefest remarks on these experiments; but one suggestion may be made, and that is that they seem to indicate that the chief movement of carbon molecules in the electric arc is *from* the negative *to* the positive carbon. The idea suggests itself that, after all, the cratering out of the positive carbon of the arc may be due to a sand-blast-like action

of this torrent of negatively charged molecules which are projected from the negative carbon. If we employ a soft iron rod as our lateral pole, we find that, after enduring for some time the projection of the arc against it, it is converted at the extremity into *steel*.

Into the fuller discussion as to the molecular actions going on in the arc, the source and nature of that which has been called the counter-electromotive force of the arc, and the causes contributing to produce unsteadiness and hissing in the arc, I fear that I shall not be able to enter, but will content myself with the exhibition of one last experiment, which will show you that a high vacuum, or, indeed, any vacuum, is not necessary for the production of the "Edison effect." Here is a carbon horseshoe-shaped conductor, not inclosed in any receiver (see Fig. 17). Close to the negative leg or branch, yet not touching it, we have adjusted a little metal plate. The sensitive galvanometer is connected between this metal plate and the base of the other or positive leg of this carbon arch.

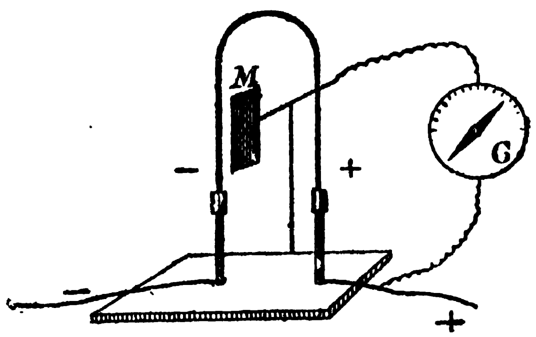

FIG. 17.—"Edison effect" experiment shown with carbon in open air.

On sending a current through the carbon sufficient to bring it to bright incandescence, the galvanometer gives indications of a current flowing through it, and as long as the carbon endures, which is not, however, for many seconds, there is a current of electricity through it equivalent to a flow of negative electricity from the plate through the galvanometer to the positive electrode of the carbon. The interposition of a thin sheet of mica between the metal plate and the negative leg of the carbon loop entirely destroys the galvanometer current.[1]

These experiments and brief expositions cover a very small portion of the ground which is properly included within the limits of my subject. Such fragments of it as we have been able to explore to-night will have made it clear that it is a region abounding in interesting facts and problems in molecular physics. The glow-lamp and the electric arc have revolutionized our methods of artificial lighting, but they present themselves also as subjects of scientific study, by no means yet exhausted of all that they have to teach.

NOTES.

PROF. E. RAY LANKESTER, F.R.S., has been elected Deputy Linacre Professor of Human and Comparative Anatomy, Oxford.

TO-DAY a meeting will be held at the Mansion House in support of the International Congress of Hygiene and Demography, which is to be held in London in 1891. The Prince of Wales has consented to act as President of the forthcoming Congress; and it is expected that the meetings will be "of great magnitude and importance." Many delegates have already been appointed, and other nominations are being received daily. It is necessary, therefore, that a definite organization should be formed, and that a fund should be raised for the defraying of expenses.

[1] This last experiment is due to my assistant, Mr. A. H. Bate.

ON Wednesday next, July 9, Prof. T. McKenny Hughes F.R.S., will deliver a lecture in the saloon of the Mansion House on the question, "Is there coal in the south-east of England?" The Lord Mayor will preside, and will be supported by the "Coal Search Committee." This Committee has been formed for the purpose of taking steps to discover whether there really are good coal-fields in the south-east of England, and, if so, to what extent. It consists of scientific and commercial men, and their services are gratuitous. Among the members are Prof. Boyd Dawkins, Colonel Godwin-Austen, Prof. A. H. Green, Dr. Henry Hicks, Mr. W. H. Hudleston, Prof. Edward Hull, Dr. A. Irving, Prof. J. W. Judd, Sir John Lubbock, Prof. Meldola, Mr. F. W. Rudler, Prof. W. J. Sollas, Mr. J. J. H. Teall, Mr. W. Topley, Mr. W. Whitaker, and Dr. H. Woodward.

A NEW scientific Society (Die Deutsche zoologische Gesellschaft, on the lines of the Anatomische Gesellschaft) has just been founded. Early in May, nine representatives of zoology in German Universities issued a circular inviting brother zoologists to unite in forming a Zoological Society. On May 28 a preliminary meeting was held at Frankfurt, and zoologists from nearly a dozen German Universities were present. At present there are fifty-four members, and the next meeting is to be held on August 1, when a President will be chosen. The invitations to this meeting will be issued early in July. Applications for membership may be sent to Prof. Bütschli (Heidelberg), Prof. Victor Carus (Leipzig), or Prof. Spengel (Giessen). The foundation of this Society is a step in the right direction, and it is to be hoped that the new Zoologische Gesellschaft will speedily become as cosmopolitan as the sister anatomical one.

THE Norwegian Storthing, by 73 votes against 39, has voted a grant of 200,000 kroner for Dr. Nansen's North Pole Expedition.

THE third summer meeting of University Extension and other students will be held at Oxford in August next. The meeting will be divided into two parts. The first part of the meeting will begin with an inaugural address by Prof. Max Müller at 8.30 p.m. on Friday, August 1, and will end on Tuesday evening, August 12. The second part of the meeting will begin on Wednesday morning, August 13, and end on Tuesday evening, September 2. This period will be devoted to quiet study. The courses of lectures will be longer than those delivered during the first part of the meeting, and will deal in greater detail with the subjects then introduced.

SIR HENRY W. ACLAND has published a letter on "Oxford and Modern Medicine." It is addressed to Dr. James Andrew, and was printed originally for private circulation. In the preface the author expresses an earnest hope that "the broad and yet precise study of material science and of nature may prosper at Oxford, as part of the whole rauge of University thought, and that in the haste for technical education our physicians may not be relegated as some now desire into a professional class or clique by themselves, but be as formerly a living part of the whole of the scientific and literary University."

THE third International Shorthand Congress will be held at Munich from August 7 to 17. The centenary of F. X. Gabelsberger, the originator of modern German shorthand, will be celebrated by those who attend the meetings, and a bronze statue of him will be unveiled.

ACCOUNTS which have reached the *Times* from the Weatherby district, in Yorkshire, agree as to the occurrence of distinct earthquake shocks on Wednesday, June 25, about 10.30 p.m., and again on Thursday morning about four o'clock. Mr. John Emmet, of Boston Spa, sixteen miles from Leeds, states that shocks were experienced, not only at Boston Spa, but at Wighill, Clifford, Thorp Arch, Weatherby, and other places, and he

adds, "Crockery was heard to shake, and some of it was broken. Those who had retired to bed felt their houses and beds shaking, and rushed into the street. . . Those who were abroad in the street had to lay hold of something to keep them from falling."

MESSRS. MACMILLAN AND CO. have nearly ready for publication two works of great interest to students of ornithology, both of American origin. The first is a treatise on the "Myology of the Raven," intended as an introduction to the study of the muscular system in birds, by Dr. R. W. Shufeldt, of the Smithsonian Institution. The second is a revised re-issue, in one volume of convenient size, of the very valuable monographs on field ornithology and on general ornithology which were prefixed to Dr. Elliott Coues's monumental "Key to North American Birds." Part I., on field ornithology, contains the necessary instructions for the observation and collection of birds in the field, and for the preparation and preservation of specimens for scientific study. Part II. is a technical treatise on the classification, the zoological characters, and the anatomical structure of the class of Birds, in which the examples cited in illustration of the principles of ornithology have for the most part been re-drawn by the author from British instead of American birds.

MESSRS. D. MARPLES AND CO., Liverpool, have issued the presidential address delivered by the Rev. Henry H. Higgins at the meeting of the Museums Association, lately held at Liverpool. In the course of the address he gives an interesting account of the principal kinds of fittings and apparatus used in the Liverpool Museum.

MESSRS. MAWSON, SWAN, AND MORGAN propose to issue a lithographed facsimile of an old manuscript volume of apothecaries' lore and household recipes, which was discovered some years ago amongst the papers belonging to the old firm of Gilpin and Company, chemists, Pilgrim Street, Newcastle. Careful examination, in which some of the curators of the British Museum have assisted, shows that the manuscript dates from about the time of Queen Elizabeth, additions having been made from time to time, in various handwritings, up to the middle of last century.

UNDER the auspices of the Royal Dublin Society, and partially aided by the Government, a scientific investigation of Irish fishing grounds is now being carried on upon the south-west and west coasts of Ireland. The Rev. W. Spotswood Green, Her Majesty's Inspector of Fisheries, Dublin, and Prof. A. C. Haddon, of Dublin, organized the expedition, which is expected to last four or five months. The screw steamer *Fingal*, of Glasgow, 160 tons register, chartered for the cruise, left Queenstown on May 7, having on board Mr. Green, Prof. Prince, Mr. T. H. Poole, of Cork, special surveyor to the expedition, and a crew of seamen experienced in trawl, net, and line fishing. Prof. Prince, who has conducted elaborate investigations upon the embryology of food-fishes at St. Andrews, and later on, Mr. E. W. L. Holt, also of St. Andrews Marine Laboratory, superintended the zoological department until Prof. Haddon was able to join the steamer. Dr. R. Scharff, of the Science and Art Museum, Dublin, and other gentlemen have temporarily assisted on board. The *Fingal* has been specially fitted up for the work. Several beam trawls (including patent forms), a quantity of mackerel nets, thirteen miles of long lines, large tow-nets (after Prof. McIntosh's pattern), microscopes and instruments for zoological and physical research, are included among the appliances. The coast from Cape Clear to Killybegs Bay (Donegal) has already been traversed, and about thirty stations have been tested and results of value obtained. In the open sea and in inshore waters the eggs and larval stages of mackerel, ling, gurnard, haddock, turbot, witch, and other species of food-fishes have been obtained, and a great variety of invertebrates, including some rare echinoderms, annelids, molluscs, &c., have been brought up in the dredge and trawl, the greatest depth tested up to this time being about 100 fathoms. The estuary of the Kenmare river, Dingle Bay, Smerwick, Birterburg, and Roundstone Bays, and the harbour of Clifden, proved to be very rich in invertebrate forms, specimens of *Synapta inhærens*, being abundant, while *Bonellia*, *Priapulus*, and many rare molluscs, *Lyonsia*, *Philine*, and various nudibranchs were procured. Copepods, larval crustaceans, medusæ, echinoderms, and ascidians occurred in such quantities as to frequently cause great inconvenience. A fine example of *Orthagoriscus mola*, nearly 9 feet in dorso-ventral measurement, was shot by Mr. Green and secured, and the rare Pleuronectid, *Arnoglossus gröhmanii*, was obtained in Clifden Harbour, the second specimen captured in British seas. Deep-sea dredgings will be taken, and it is expected that the reports, to be presented at the end of the cruise to the Royal Dublin Society, to the Irish Fishery Department, and the Government, will be of unusual scientific interest.

SOME valuable notes on the progress of the coloured people of Maryland since the American civil war have been printed in the series of "Johns Hopkins University Studies in Historical and Political Science." The author is Dr. J. R. Brackett. He takes a more favourable view of the subject than is adopted by many American observers, and deprecates the idea of good citizens allowing "the coloured people to be condemned before the testimony is all in, at a fair, unbiassed trial." There are now a good many schools for coloured children, and conventions of coloured teachers are held. The most discouraging fact in connection with the progress that has been made is that everything has been gained by the energy of a few leaders. The coloured people, according to one of themselves, are "too spasmodic"; they are "too prone to grow tired in well doing."

THE Town Gardening Committee of the Manchester Field Naturalists' Society, to which we lately alluded, has been vigorously prosecuting its work. The esplanade in front of the Manchester Infirmary and Albert Square, in which the Town Hall stands, are now decorated with seventy-five beautiful specimens of holly and aucuba, whose bright green leaves show up with good effect against the darkened stone of the neighbouring buildings. The plants have been placed in substantial but movable boxes 3 feet square and 4½ feet in height. The Parks Committee of the Manchester Corporation, of which Mr. Chesters-Thompson is chairman, has shown a laudable anxiety to carry out the plans suggested, and has contributed the greater part of the £500 already spent by the two committees on plants. It is hoped next year to carry on tree-planting on a large scale in the open spaces and streets of Manchester, and with a view to ensuring success under the extremely unfavourable atmospheric conditions peculiar to the city, the Town Gardening Committee is occupied in collecting all information relating to the subject, and will shortly issue a pamphlet of recommendations to those actually engaged in the work. Dr. Bailey, of Owens College, will contribute an essay on the effect of noxious gases on plants, and Dr. Poisson, of the Museum in Paris, will send a detailed account of the progress and experience gained in tree-planting in French towns. Several of our most distinguished botanists have also consented to act as corresponding members of the committee. It is probable that the movement will spread rapidly over the north of England, as the committee has already received official and unofficial requests for information about the work from Liverpool, Carlisle, Leek, and many other towns. The honorary secretary, Mr. C. J. Oglesby (16 Kennedy Street, Albert Square, Manchester), will be glad to receive additional information from anyone who may have had experience in the cultivation of trees and plants in manufacturing towns.

AMONG the papers read at the closing meeting of the Royal Society, was one by Prof. Ewing, of the Dundee College, entitled, "Contributions to the Molecular Theory of Induced Magnetism," in which experiments of a novel and curious kind were described, leading to an important conclusion. Prof. Ewing has examined experimentally Weber's theory of molecular magnets, according to which the molecules of iron are always magnets, which point anyhow in an unmagnetized piece, but are turned round to point one way when the iron is magnetized. It is well known that in the development of this theory by Maxwell and others there has been much difficulty in reconciling the results of the theory with what is known about the magnetic quality of iron and steel, and many arbitrary assumptions have been suggested in order to make the theory fit the facts. Prof. Ewing's experiments have removed this difficulty, showing that no arbitrary assumptions are necessary, and that the known character of the magnetizing process may be deduced from the molecular theory in its simplest form. The experiments were made by means of a model in which a large number of small pivoted permanent magnets are grouped to represent the molecular structure of iron. When a magnetic field is applied, the action of the small magnets on one another makes them behave in a way that exactly agrees with the observed behaviour of a bar of solid iron when it is magnetized. The model exhibits all the variations of susceptibility which are known to take place, and explains how magnetic hysteresis occurs without anything like friction among the molecules.

ACCORDING to the *Ceylon Observer*, Mr. A. T. W. Marambe, of Kandy, the translator of "Gulliver's Travels" and the author of "A Practical Synopsis of Ceylon History," has in preparation a little work on the Veddah language. Many have attempted this task before, but without success. Besides Veddah songs, a description of habits and customs, &c., the book will have a completer list of words than has hitherto appeared.

AN exceptionally pretty and instructive series of new experiments, upon the action of carbon heated to whiteness in the electric arc on various gaseous compounds, are described in the current number of the *Berichte* by Prof. Lepsius, of Frankfurt. Perhaps the most important are a group of four experiments illustrating the relative combining powers of the four elements iodine, sulphur, phosphorus, and carbon. The apparatus employed consists of a specially modified Hofmann eudiometer, one limb of which is 40 mm. in diameter and 300 mm. long, and the other longer limb narrower and furnished with a mercury reservoir at its upper end. The wider limb, which is the reaction-tube, is furnished with a stop-cock at the top, and just below this are two tubuli through which the adjustable carbon poles are inserted. At the base of the wider limb a second stop-cock is placed so as to permit of the adjustment of the mercury. The gas to be experimented upon is introduced into the apparatus at the upper stop-cock by allowing mercury to run out at the base. Four such eudiometers are arranged in a row, and 100 c.c. of gas introduced into each. Into the first, hydriodic acid is introduced; into the second, sulphuretted hydrogen; into the third, phosphuretted hydrogen; and into the fourth, marsh-gas. The gases thus stand at the same level in each of the four reaction-tubes. The current from a battery whose electromotive force should amount to 60–80 volts is then allowed to pass between the carbon poles, which are, of course, in contact at first, and then gradually drawn away until the maximum arc is obtained. Each reaction may be performed separately, or all four may be allowed to proceed simultaneously by adopting an arrangement in multiple arc. In hydriodic acid the brilliant arc light is tinted a magnificent purple and the whole space above the mercury becomes filled with violet vapour of iodine. Notwithstanding the considerable heating effect of the discharge, the volume of gas perceptibly diminishes, the liberated iodine rapidly depositing in minute crystals upon the walls of the tube. So rapid, indeed, is the diminution in volume, that mercury requires to be poured into the reservoir to prevent the entrance of air into the reaction-tube. In a very few minutes the reaction is complete, and the mercury ceases to rise. In sulphuretted hydrogen the light is coloured blue, and copious clouds of sulphur are produced, which settle upon the walls in the form of a white transparent coating. The volume of gas is considerably augmented, owing to the expansion by heat, and the reaction is likewise completed in a very brief space of time. In phosphuretted hydrogen the arc glows with a dazzling red light; the volume visibly augments at a rapid rate, and red clouds of phosphorus are thrown off, the glass walls being covered with red phosphorus, among which are to be found notable quantities of the ordinary yellow variety. The mercury attains its maximum height in the narrow limb in a minute at most from the moment of switching on the current. In the case of marsh-gas, the whiteness of the arc appears at first to be rendered more intense, and is surrounded by dense black clouds of carbon, which form a striking background. The upper part of the vessel, however, soon becomes covered with an opaque deposit, which perceptibly diminishes the brilliancy of the light. The volume appears to increase by leaps and bounds, and in a few seconds attains its maximum. At the end of the experiment, after cooling, the volume of hydrogen left in the first case is 50 c.c., in the second 100 c.c., in the third 150 c.c., and in the fourth case 200 c.c., thus showing in a most striking manner that an atom of iodine combines with one atom of hydrogen, sulphur with two, phosphorus with three, and carbon with four atoms of hydrogen.

THE additions to the Zoological Society's Gardens during the past week include a Bosman's Potto (*Perodicticus potto*) from West Africa, presented by Mr. P. S. S. Radcliffe; a Harnessed Antelope (*Tragelaphus scriptus* ♂), a —— Antelope (*Cervicapra* sp. in. ♂), two Marabou Storks (*Leptoptilus crumeniferus*) from Gambia, West Africa, presented by Dr. Percy Rendall; an English Wild Bull (*Bos taurus*, var.) from Chartley, Staffordshire, presented by the Earl Ferrers; a Ring-tailed Coati (*Nasua rufa* ♀) from Buenos Ayres, presented by Mr. C. W. Blacklock; two Tigers (*Felis tigris* ♂ ♀) from India, presented by H.R.H. the Duke of Clarence and Avondale; a Wedge-tailed Eagle (*Aquila audax*) from Australia, presented by Captain Salvin; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. Alexander Finlay; two Nightingales (*Daulias luscinia*), British, presented by Mr. J. Young, F.Z.S.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on July 3 = 16h. 47m. 29s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4373	—	Greenish-blue.	17 58 19	+66 37
(2) 387 Birm.	5 6	Reddish-yellow.	16 40 33	+ 8 47
(3) π Herculis	3	Yellow.	17 11 12	+36 56
(4) ε Herculis	3·4	Bluish-white.	16 56 6	+31 5
(5) 202 Schj.	8	Very red.	17 23 15	−19 24
(6) V Boötis	Var.	Reddish-yellow.	14 25 20	+39 21

Remarks.

(1) This is the planetary nebula famous in the history of astronomy as the first nebula which was examined by the spectroscope. The nebula, though small, is remarkably bright, and the lines in its spectrum are at least as bright as those in the nebula of Orion. The three principal lines in the green, and the hydrogen line at G, are seen without any difficulty.

Vogel mapped two faint lines near λ 518 and 554, but these require confirmation. With a 10-inch refractor I have had no great difficulty in glimpsing these fainter lines, but I was unable to confirm their positions. The line at 518 is very suggestive of carbon, and that at 554 of manganese, and, if possible, comparisons with these substances should be made where a large aperture is available. I have very little doubt also, from my own observations, that there are many lines between F and G. Another observation of importance will be that of the character of the brightest line. Observers differ very considerably on this point, some maintaining that it is perfectly sharp on both edges, and others that it is softened off on the more refrangible edge. For this observation it is not desirable to use high dispersion. In the General Catalogue the nebula is described thus:—"A planetary nebula; very bright; pretty small; suddenly brighter in the middle to a very small nucleus." Webb compares the telescopic appearance of the nebula with that of a star out of focus.

(2) Vogel describes the spectrum of this star as a very fine one of the solar type (Class II.*a*), whereas Dunér calls it Group II. According to the latter observer the banded spectrum is feebly developed, 2, 3, and 7 being very narrow, and the remaining bands appearing only as lines. From these observations it is not possible to say whether the star belongs to an early species of the group or a late one. In either case the bands would be narrow, but if the star be at an early stage the bright carbon flutings ought to be very manifest, and if at a late stage, there ought to be dark lines in addition to the narrow bands. Vogel may have mistaken the narrow bands for lines.

(3 and 4) These are stars of the solar type and of Group IV. respectively. The usual detailed observations are required in each case.

(5) This star, according to Dunér, has a well-marked spectrum of Group VI., the blue zone, however, being very feeble. The green and yellow zones are separated by a wide and dark band; the bands 4 and 5 are not visible. Further details or peculiarities should be looked for.

(6) This variable has a well-marked spectrum of Group II. (Dunér). The range is but small—7·0–9·4 in a period of 266 days—and it will be interesting to ascertain whether the bright hydrogen lines appear at maximum as in stars of greater range. Dunér states that though the spectrum is not a very bright one, its characteristics are by no means difficult to observe. There will be a maximum about July 6.

A. FOWLER.

ANNULAR ECLIPSE OF JUNE 17.—The number of the *Comptes rendus* for June 23 contains observations of this eclipse made at various Observatories. The Emperor of Brazil took the time of second contact at Nice Observatory; MM. Charlois, Javelle, and Perrotin those of first and last contact. At Lyons Observatory, M. Gonnessiat made some measures of the position-angle of the shadow. M. Trépied at Algiers succeeded in taking 26 photographs, the times of first and last contact also being noted. The maximum of the eclipse was indicated on the curves of a self-registering thermometer by a fall in temperature of 1°·4. Clouds prevented good observations at Meudon, but four photographs were taken by M. Trouvelot. M. de la Baume went from Meudon Observatory to Canea to observe the eclipse, and a telegram was received from him by M. Janssen stating that the weather was favourable, and that he had been able to obtain photographs of the ring and of its spectrum. M. Janssen also noted that one of the objects of the expedition to Canea was to obtain a photographic spectrum of the annulus, in order to see if the spectrum of the extreme edge of the sun's disk showed the bands of oxygen, and from the telegram received it seems probable that the question will be settled. The photographs obtained at Meudon show the granular structure of the solar surface so well visible during an eclipse, and the granulation can be traced right up to the edge of the moon, thus affording another proof of the excessive rarity of the lunar atmosphere.

YARNALL'S STAR CATALOGUE.—The Catalogue of stars observed at the United States Naval Observatory during the years 1845 to 1877, and prepared for publication by Prof. M. Yarnall, has been revised and corrected, and the stars renumbered by Prof. Edgar Frisby. In preparing this edition a re-examination of all annonymous stars has been made; the named stars have been compared with those of existing catalogues, the names being changed whenever necessary, and new names that existed previous to the publication of the Catalogue have been supplied. The errata in previous editions, pointed out by Profs. Holden, Krueger, and Millosevich, and Dr. Peters, have also been corrected, and the many notes to the Catalogue referring to the mistakes in the second edition, and the changes that have been made, indicate that the task of revision has not been a light one. As the object of the revision was merely for the purpose of correcting mistakes, no observations have been added or any unfinished observation completed, excepting such as were observed but omitted from the Catalogue, the apparent additions being found in some of the published volumes or in an unfinished state in the observing-books. The stars in the Catalogue have all been compared with standard catalogues as far as possible, and Prof. Frisby confidently believes that most of the mistakes have been corrected.

PHOTOGRAPHS OF THE SURFACE OF MARS.—Prof. W. H. Pickering, in the June number of the *Sidereal Messenger*, makes some remarks on fourteen photographs of the planet Mars taken by Mr. Wilson. Seven negatives were taken on April 9, between 22h. 56m. and 23h. 41m. G.M.T., and seven more were taken on April 10, between 23h. 20m. and 23h. 32m. Thus the same face of the planet was presented in both cases. Distinct and identifiable spots and markings are well shown in all the photographs, but in those taken on the latter date the white spot surrounding the south pole is seen considerably larger. It has been known for some years that the size of these polar spots varied gradually from time to time, apparently diminishing in the summer and increasing in the winter of their respective hemispheres. This, however, appears to be the first time that the precise date and approximate extent of one of these accessions has been observed. The appearances described are said to be so conspicuous upon each of the fourteen photographs that no one who had once seen them would have any difficulty in deciding on which of the dates any particular plate was taken.

LIGHTNING SPECTRA.—Mr. W. E. Woods, of Washington, has used a Browning's pocket spectroscope to study the spectrum of lightning during a thunderstorm (*Sidereal Messenger*, June 1890). In several instances he observed what appeared to be bright lines superposed on a faint continuous spectrum; and in each case, when the continuous spectrum was bright enough to be seen, shaded flutings were visible. It is, however, much to be regretted that no diagram or statement as to the approximate position of the lines and fluting is given.

THE MARINE BIOLOGICAL ASSOCIATION.

AT the annual general meeting of the Marine Biological Association, held at the rooms of the Royal Society on Wednesday, June 25, the following Report was submitted by the Council, and unanimously adopted. We omit only the list of those who went as a deputation to the Chancellor of the Exchequer on May 15.

The Council has met nine times during the past year, and the attendance has been fully up to the average of previous years.

The business transacted by the Council has had reference—

(1) To the maintenance and general efficiency of the Laboratory.

(2) To the prosecution of special investigations on economic subjects.

(3) To the financial position of the Association.

(1) It was found necessary to alter the communications between the storage reservoirs and the pumps of the Laboratory at Plymouth, and orders were given to Messrs. Leete, Edwards, and Norman, to supply a new valve-box, connection-pipes, &c. The cost of these alterations has been considerable, but it is satisfactory to note that the results have been very beneficial, and have produced a marked improvement both in the working of the pumps and in the water in circulation.

The Director reports that there was some little trouble over the sea-water in June and July 1889, during the hot weather, and during the alterations to the supply-pipes, which prevented more than one of the storage reservoirs being in use; but that since then, and especially after the alterations were completed, the water has been of admirable quality, and all the animals have done remarkably well.

Great improvement has lately been effected in the Aquarium at a very trifling cost, by hanging curtains between the top of the

fronts of the tanks and the ceiling, so that all the light reaching the spectator must pass through the tanks. Previous to this there appears to have been an excess of light in the tanks, and the fishes now appear to be much more comfortable, and keep nearer to the glass fronts.

The following fishes, molluscs, and crustacea have spawned in the tanks during the past year:—

The Plaice (*Pleuronectes platessa*).
The Flounder (*Pleuronectes flesus*).
The Pouting (*Gadus luscus*).
The Poor Cod (*Gadus minutus*).
The Rockling (*Motella tricirrata*).
The Lucky Proach (*Cottus bubalis*).
The Spotted Dog-fish (*Scyllium canicula*).
Chiton cinereus.
The Whelk (*Buccinum undatum*).
The Purple (*Purpura lapillus*).
The Sea-hare (*Aplysia punctata*).
The Sea-lemon (*Archidoris tuberculata*).
Goniodoris nodosa.
The Lobster (*Homarus vulgaris*).
The Crawfish (*Palinurus vulgaris*).
The Shrimp (*Crangon vulgaris*).
The Prawn (*Palæmon serratus*).
Idotea tricuspidata and *emarginata*,

as well as other species not so well known.

The *personnel* of the staff and servants remains unchanged, with the exception of the fisherman, W. Roach, who left in October. His place has been filled by E. G. Heath, a trawl fisherman of great experience.

The Council sanctioned the purchase, in July 1889, at a cost of £250, of a small steam-launch, the *Firefly*, which has been of great service. Being half-decked, and only 38 feet long, this launch is only suitable for local expeditions, and its purchase in no wise diminishes the necessity for a sea-going steam-vessel for carrying on investigations on food-fishes. The *Firefly* is very economical in coal and water, and has entailed no extra expense in working. The Association now possesses three boats, the *Firefly*, the *Mabel*, a three-ton hook and line fishing-boat presented by Mr. Bourne, and the *Anton Dohrn*, a rowing-boat bought in 1889.

Trawling, dredging, surface netting, and shore hunting have been carried on continuously during the year, and examples of interesting species, many of which are new to the district, have been added to the list since the last Report.

The standard collection of species is making good progress, the collection of Decapod Crustacea being remarkably complete.

(2) The researches on food-fishes and crustacea carried on under the direction of the Council have made considerable progress.

The Director of the Association, Mr. G. C. Bourne, has continued his observations on the pelagic fauna in the neighbourhood of Plymouth, and was also able, through the courtesy of Captain Aldrich, R.N., to make an expedition off the south-west coast of Ireland in H.M.S. *Research* in July last, for the purpose of comparing the surface fauna at the entrance of the Channel with that of the Channel itself. Some interesting observations have been made in connection with the presence of multicellular floating algæ in spring months and the presence of mackerel, which it is hoped may lead to practical results.

The Director has made observations and collected notes on the destruction of immature fish in various localities, and has been able, with the kind co-operation of the medical staff of the Deep Sea Mission to Fishermen, to arrange an extensive inquiry into the presence of immature fish in deep waters in the North Sea, their movements and destruction by beam trawling. This inquiry is in progress, and promises to be full of interest.

In connection with the destruction of immature soles in the estuary of the Thames, the Director has been making arrangements for keeping young soles in inclosed ponds with the view of rearing them to a marketable size, as is done in the Adriatic. For various reasons these experiments have been delayed, and are not yet in progress.

Experiments are also being made on the possibility of cultivating soles in fresh water, and it has been proved that the adult sole may be kept in fresh water.

In conjunction with Dr. G. H. Fowler, the Director has studied the natural history of the oyster, and through the kindness of Lord Revelstoke he has been able to arrange a series of practical inquiries on the natural history and propagation of the oyster in the River Yealm.

The Naturalist of the Association, Mr. J. T. Cunningham, has been chiefly occupied during the past year with a treatise on the common sole, which is now ready for publication.

Mr. Cunningham also has gathered much valuable information about the occurrence of the anchovy in English waters, and the possibility of an English anchovy fishery. A full account of the anchovy is given in the last number of the Journal, vol. i. No. 3.

In the early spring of this year, Mr. Cunningham made several expeditions to procure the ova of soles and other flat-fishes. He was able to secure and artificially fertilize a much larger number of soles' ova than on any previous occasion, and the fertilized ova were successfully hatched and the larvæ reared, up to the period of the absorption of the yolk-sac, in the aquarium.

On March 13 this year the plaice in the aquarium were found to be breeding. The Director and Mr. Cunningham collected a large number of their fertilized ova and transferred them to suitable hatching apparatus. The ova hatched out by March 18, and the larvæ were kept alive in specially isolated tanks till April 2. By this time the yolk-sac was completely absorbed, but the larvæ, although apparently healthy, could not be induced to feed. They died off very suddenly, evidently for want of food, on April 3 and 4, having lived fifteen days after hatching.

A second batch of ova was procured on March 28, and the eggs were hatched out on April 3 and 4. These larvæ were placed in a tank and fed with the pelagic organisms caught in the tow-net. They paid no attention to this food, so on April 22 they were fed with crushed crab, which they appeared to like, for on the following day their intestines could be seen full of food. In spite of this they began to die on April 24, and all were dead by the 26th.

Thus in the second experiment the larvæ were kept alive twenty days after hatching, a considerably longer period than in previous experiments at Plymouth, and, what is more important, they were induced to feed. These experiments show that some steps have been made towards success. None of the larvæ underwent metamorphosis, but Mr. Cunningham has procured some young plaice, flounders, and brill, already "flattened," and these are thriving in the tanks and feeding regularly.

Arrangements have been made with the Fishery Board for Scotland for carrying on an investigation on the food of the common sole, in connection with the work done by the Board on the food of other fishes.

Mr. W. Bateson was working on the sense-organs and habits of fishes, with the view of showing the possibility of using artificial or preserved baits in sea-fishing, from April to October 1889. The results of Mr. Bateson's investigations have been published in the Journal, vol. i. No. 3.

Mr. Weldon continued his investigations on the artificial rearing of lobsters last year. His experiments were apparently turning out successfully, when an accident caused the loss of his larvæ and apparatus. This year the artificial rearing of lobsters is being proceeded with by means of a different form of apparatus suggested by Dr. Fowler's successful method of raising the young of *Idotea*.

In addition to his experiments on lobsters, Mr. Weldon is engaged on important scientific investigations on the variation and natural history of the Decapod Crustacea, his expenses being, as before, met by the grant of £150 from the Government Grant Fund of the Royal Society, intrusted in 1887 by the Government Grant Committee to the President of the Association, the Hon. Secretary, Prof. Moseley, and Mr. Sedgwick.

The following gentlemen and ladies have been engaged on independent scientific researches in the Laboratory since the date of the last Report:—

Dr. G. H. Fowler (Studies in Descent), Mr. M. C. Potter (Marine Algæ), Mr. S. F. Harmer (Development of *Polyzoa*), Mr. T. T. Groom (*Cirrhipedia*), the Rev. Canon A. M. Norman, D.C.L. (Crustacean Fauna), Mr. A. O. Walker (*Amphipoda*), Prof. T. Johnson (*Florideæ*), Mr. A. E. Shipley (*Gephyrea*), Dr. Hans Driesch, Jena (Heliotropism in *Hydroidea*), Mr. P. C. Mitchell (Histology of *Tunicata*), Mr. T. H. Riches (Nephridia of *Mollusca* and *Crustacea*), Mr. Herbert Thompson (Development of *Crustacea*), Miss Marion Greenwood, Newnham College, Cambridge (Physiological Studies), Miss L. Ackroyd, Newnham College, Cambridge (Morphology of *Nebalia*).

(3) Among the receipts of the past year the Council have to acknowledge the following subscriptions and donations:—£100 from Lord Revelstoke; £100 from Sir Henry Thompson; £100 from the Grocers' Company; £200 from the Fishmongers' Company (annual grant for five years); £500 from H.M. Treasury (annual grant for five years).

From annual subscriptions and compositions £143 was received, £61 interest on investments, and £150 for rent of tables and sale of specimens.

The expenditure, as shown in the Treasurer's account presented herewith, amounted to £2992, of which £398 was paid to Mr. Inglis for balance of his fees as engineer, £417 for structural alterations and additions, £112 for bait investigation, and £250 for a steam-launch.

The Association now has in hand, in cash and invested, £1398 2*s.* 11*d.*

The Council have great pleasure in acknowledging the generous assistance which has lately been afforded to the Association by the Fishmongers' Company, by Mr. J. P. Thomasson, M.P., and Mr. Frank Crisp.

The Fishmongers' Company, in addition to substantial grants which they have already made to the Association, have undertaken to contribute £400 per annum to the funds of the Association for a period of five years from the present date.

Mr. J. P. Thomasson has kindly offered a sum of £250, to enable the Council to retain the services of the Naturalist, Mr. J. T. Cunningham, for another year.

Mr. Frank Crisp has kindly given a sum of £120 (£60 per annum for two years) to meet the expenses of special investigations on the culture of sea fishes in inclosed ponds. The Council take this opportunity of placing on record their appreciation of the interest and confidence shown in the work of the Association by these liberal donations.

The thanks of the Association are due to Prof. Haeckel for a copy of his work on the *Siphonophora*; to Colonel Richardson, R.A., for a number of ichthyological works from the library of the late Sir J. Richardson; to Mr. J. W. Clark for back numbers of the Philosophical Transactions of the Royal Society and other books; to Messrs. J. and A. Churchill for the current numbers of the *Quarterly Journal of Microscopical Science*; and to Messrs. Agassiz, Giard, Marion, the United States Fish Commission, the Naples Zoological Station, the officers of the Norwegian North Atlantic Expedition, and other individuals and societies for copies of their publications.

The Council desire to express the indebtedness of the Association to the Council of the Royal Society for kindly permitting the Association to hold the periodical meetings of the Council and Association in their rooms.

In July and August 1889, the Council was in correspondence with the Fishery Board for Scotland and the Fisheries Department of the Board of Trade, with reference to the possibility of procuring scientific information on the alleged destruction of immature fish by beam trawling in deep waters.

Subsequently the Council determined to make an application to H.M. Treasury for a further grant of money in aid of special researches on food-fishes. The Chancellor of the Exchequer kindly consented to receive a deputation on the subject on May 15. . . .

The Council regret to have to announce that Prof. Huxley, who since the foundation of the Association has been its President, has found it necessary to withdraw from the office which he has held with so much honour and advantage to the Association. The Council desire to express their warm appreciation of the eminent services rendered by Prof. Huxley to the Association, and their great regret that he should be unable to continue his office.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

VICTORIA UNIVERSITY.—Last Saturday was Degree-day; the ceremony, presided over by Principal Rendall, the Vice-Chancellor, took place in the Manchester Free-Trade Hall. In the course of his speech, the Vice-Chancellor gave the following details as to the progress of the University:—

"A three-fold scheme for certificates, technical, commercial, and literary, has replaced the narrower project for technical certificates alone, and will be the means of giving University direction and attachment to numerous organizations which have hitherto lacked clearness of aim or recognition of results. The Manchester Chamber of Commerce has entrusted the examinations for its commercial certificate to the University. The local lectures scheme continues to thrive vigorously. In the last three sessions 21 courses, with an average attendance of 130, the large majority in or near Manchester, have been delivered under University auspices. The three colleges of the University are taking action, more or less concerted, for the establishment of day training colleges for primary teachers under the provisions of the new Education Code. Thus step by step the University is comprehending her mission and entering upon her heritage. Those who are forwarding the work may feel that impatience for quick returns which comes of convictions confident and energetic, but the observer and the historian will agree that in content and scope Victoria University has advanced with unparalleled rapidity. In all the colleges of the University building is in progress or in contemplation. At University College the Victoria Building for the arts department is advancing towards completion; at Yorkshire College funds have been raised for the erection of a medical department and other needed extensions; at Owens College further enlargement of the Medical School buildings is now under consideration."

As at Cambridge, the women students have done remarkably well this year, three out of four "first classes" in the B.A. honours schools and the Thomasson Prize for English Essay falling to their share.

ST. ANDREWS UNIVERSITY.—A Scholarship of the value of £30 a year has just been placed at the disposal of Prof. Percy Frankland at University College, St. Andrews University, by Miss E. F. Forster, of London. It is intended that the student holding the same shall devote the whole of his time to the prosecution of original research. The Scholarship, which will be known as "The Forster Research Scholarship," has been awarded for this year to Mr. John MacGregor, M.A.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 12.—"On the Position of the Vocal Cords in Quiet Respiration of Man, and on the Reflex-Tonus of their Abductor Muscles." By Felix Semon, M.D., F.R.C.P., Assistant Physician in charge of the Throat Department of St. Thomas's Hospital, and Laryngologist to the National Hospital for Epilepsy and Paralysis, Queen Square. Communicated by Prof. Victor Horsley, F.R.S.

The final conclusions arrived at by the author are as follows:—

(1) The glottis in man is wider open during quiet respiration (inspiration and expiration) than after death or after division of the vagi or recurrent laryngeal nerves.

(2) This wider opening during life is the result of a permanent activity of the abductors of the vocal cords (posterior crico-arytænoid muscles), which therefore belong not merely to the class of accessory, but of regular respiratory, muscles.

(3) The activity of these muscles is due to tonic impulses, which their centres receive from the neighbouring respiratory centre in the medulla oblongata. It is very probable that these impulses rhythmically proceed to the respiratory centre from the stimulation of certain afferent fibres contained mainly, but not exclusively, in the trunks of the pneumogastric nerves, and that they are in the respiratory centre changed into tonic impulses. The regular activity of the abductors of the vocal cords during life, therefore, belongs to the class of reflex processes. The permanent half-contraction of these muscles, in which form their tonic innervation is manifested, can be further increased, in concord with the general laws of the mechanism of respiration, by either volition or other reflex influences.

(4) In spite of their extra-innervation, the abductors of the vocal cords are physiologically weaker than their antagonists.

(5) These antagonists, the adductors of the vocal cords, have primarily nothing at all to do with respiration, and ordinarily serve the function of phonation only. Their respiratory functions are limited to—

(*a*) Assistance in the protection of the lower air passages against the entry of foreign bodies.

(*b*) Assistance in the modified and casual forms of expiration known as cough and laughing.

Physical Society, June 6.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Mr. H. Tomlinson, F.R.S.. read a paper on the effect of change of temperature on the Villari critical points of iron. This, he said, was a continuation of the paper he read before the Society on March 21, and the method employed was the same as then described (see *Phil. Mag.*, vol. xxviii. p. 394). Since then, however, he has made experiments at various temperatures up to 285° C., the temperature being determined from the resistance of a platinum wire whose temperature coefficient was carefully determined. The following table shows some of the results obtained with a well-annealed iron wire 1 mm. in diameter, which had been repeatedly heated up to 300° C., and cooled to the temperature of the room until the temporary permeability with various loads attained constant values at both temperatures.

Magnetizing force in C.G.S. units.	Load in kilogrammes for which permeability is the same as for unloaded wire at temperature				
	12° C.	76° C.	167° C.	244° C.	285° C.
2·84	4·7	5·0	5·3 and 12	5·7 and 10	None
3·70	2·5	3·2	3·6	4·2 ,, 11·5	4·7 and 9·9
4·8	1·8	2·5	2·7	—	3·1 ,, 12·3
7·69	None	None	None	None	None
10·40	,,	,,	,,	,,	,,
15·32	,,	,,	,,	,,	,,

Curves from which these numbers were obtained are given in the paper, and in these the load in kilogrammes, and percentage change of temporary permeability are plotted. From these curves and table it will be seen that if the first points in which the curves cut the load-line be considered, then at all temperatures the Villari values increase as the load decreases. If, however, the second points be taken, the critical values increase both with load and temperature. In both cases the Villari value is increased by rise of temperature. From the curves it follows that rise of temperature reduces the total variation of permeability produceable by loading. A table showing the temporary permeability of the unloaded wire at the various temperatures accompanies the paper.—A paper on the diurnal variations of the magnet at Kew, by W. G. Robson and S. W. J. Smith, was communicated by Prof. Rücker. In some preliminary remarks the Professor pointed out the great advisability of having the results of magnetic observations at various Observatories reduced and published in the same manner, and for the same periods. In order that this may be effected, the methods of reduction must be trustworthy, but not very elaborate. The Greenwich plan is too laborious to be generally adopted, but the method suggested by Dr. Wild (Rep. Brit. Ass., 1885, p. 78), in which the mean diurnal variation is obtained from measurements on five quiet days in each month, is feasible. With a view to further testing the trustworthiness of this method, the work described in the paper was undertaken. Mr. Whipple had made a comparison of the two methods for the years 1870–71–72, with the result shown in the following table:—

Minutes of arc.

$$K_s - K_w = 0·7$$
$$G - K_s = 1·2$$
$$G - K_w = 1·6$$

where K_s is the mean diurnal range at Kew as obtained by Sabine's method, K_w that obtained by Wild's method, and G that obtained at Greenwich by the Greenwich method. He also found that the mean hourly differences followed some definite law. The authors undertook the reduction of the Kew observations according to Wild's method for the years 1883, 1886–87; the first was chosen as being a year of maximum sun-spots. The results give—

Minutes of arc.

1883 ... $G - K_w = 1·5$
1886 ... $G - K_w = 1·2$
1887 ... $G - K_w = 1·9$

There is thus a difference of nearly two minutes in the variations at the two places, and this cannot all be accounted for by the method of reduction. Another peculiarity is that the range, as calculated by Wild's method, is greater by about 0'·5 than that obtained by the Greenwich method, although the latter includes days of moderate disturbance. The total range at both places has diminished by about 1'·6 between 1883 and 1887. The paper is accompanied by tables and curves plotted from the differences in the mean hourly readings at Greenwich and Kew for each of the above 6 years, and a marked similarity exists between all of them. The mean of the 6 curves differs in no case by more than 0'·4 from the curve for any year. It is thus possible to calculate the Greenwich values from the Kew numbers; and as these latter are published about two years sooner than the former, this fact may be very important. Referring to the reduction of results, Prof. Rücker said that the Stonyhurst observers and Prof. Mascart were willing to adopt Wild's method; Falmouth, he hoped, would follow suit, and Greenwich had been asked to publish their results in both ways. Mr. Whipple said that, before recording-instruments were available, and the numbers were obtained from separate experiments, the labour involved was considerable, and a single large disturbance or magnetic storm might vitiate the result of a whole year's work. Methods were therefore adopted to eliminate these disturbances; of these, that used by Sabine may be particularly mentioned. Although declination records have now been obtained for a considerable number of years, the cause of the variations still remains unknown. They do not seem to be dependent on temperature or on astronomical facts. He considered it valuable to obtain magnetic data from different parts of the earth, but comparisons were only possible when all are published on the same plan. This, he hoped, would result from the efforts of Profs. Rücker and Adams. When this is accomplished, the observations on magnetic force will need treatment; this work will be laborious, and the aid of volunteers like Messrs. Robson and Smith would be of great service. Prof. W. G. Adams said he was glad to see the satisfactory nature of the work which had just been brought before the Society. Usually, the mass of figures to be dealt with was so large that the mere reduction was a great undertaking. If, however, the difference between results obtained by the Greenwich and Wild's method was not more than 0'·4, it may be possible to make out the causes of the variations from observations reduced on Wild's plan. He himself would put more faith in horizontal force observations, and wished they could be worked out by some ready method. He hoped the one adopted in America, of obtaining mean curves by photography, might prove satisfactory. Prof. Perry asked if a machine could not be made to do the work. Mr. Whipple said such machines had been used by the Meteorological Office, but they were so elaborate and expensive that clerical work was just as cheap. The method of photographing mean curves had been tried at Kew, but it was open to the objection that accidental disturbances, such as those produced by the movement of iron in the vicinity and the approach of cabs, &c., were not eliminated. Mr. Boys, referring to the use of integrators, said that, for an harmonic analyzer, his disk-cylinder pattern was preferable to the ball-disk-cylinder integrators of J. Thomson, for it was much cheaper, and had less inertia. The President said the movement initiated by Prof. Rücker would be of great service if it resulted in the numbers obtained at the various magnetic Observatories being published in the same way. It was a great advantage to have such men, who were not permanently attached to an Observatory, to take up the subject and suggest improvements. The heads of such institutions were usually too much employed in making the necessary reductions to have time for devising improved methods. In his opinion, greater freedom should be allowed to the chiefs of Observatories, for it should be borne in mind that the object of observations is not to produce volumes of figures, but to increase our knowledge. Referring to the reduction of observations, he thought the voluntary services of senior physical students should be more generally accepted, and to this end he suggested that properly recommended persons should be allowed to spend some time in Observatories as honorary assistants. This would be of great use to the students themselves, and an advantage to the Observatories, for the reduction of observations could then be expedited. As regards the accidental disturbances referred to by Mr. Whipple, he contended that regulations should be adopted to render them impossible.

Zoological Society, June 17.—W. T. Blanford, F.R.S., in the chair.—Mr. Sclater exhibited and made remarks on a mounted head of a Pallah Antelope, obtained by Captain F. Cookson, on the Cunene river, in South-western Africa, which was distinguished by its black face from the ordinary form of the Cape Colony.—Mr. Sclater also exhibited a large photograph of Grévy's Zebra (*Equus grevyi*), taken from the specimen in the

Natural History Museum at Paris by Mr. Gambier Bolton.—A specimen of Pallas's Plover (*Ægialitis asiatica*), obtained in May last near Great Yarmouth, and now in the Norwich Museum, was exhibited; and a note upon its occurrence by Mr. T. Southwell was read to the meeting.—A communication was read from Prof. F. Jeffery Bell containing some notes received from Mr. Edgar Thurston, of the Madras Museum, on the habits of the Pennatulids of the genus *Virgularia*.—A communication was read from M. P. A. Pichot, containing exact particulars of the locality on the Lower Rhone in which the Beaver is still found in its native state.—Mr. W. Bateson read a paper on some cases of repetition of parts in animals, and exhibited a series of specimens illustrative of this subject.—Mr. Henley Grose Smith gave an account of the Diurnal Lepidoptera collected by Mr. W. Bonny, of the Emin Relief Expedition, on the river Aruwimi, Central Africa.—A communication was read from Mr. W. L. Distant, containing descriptions of some Hemiptera collected by Mr. W. Bonny during the same expedition.—A communication was read from Mr. H. W. Bates, F.R.S., on some of the Coleoptera collected by Mr. W. Bonny during the same expedition.—Mr. Herbert Druce read the descriptions of ninety-five new species of Lepidoptera Heterocera from Central and South America.—Mr. G. A. Boulenger pointed out the secondary sexual characters in the South African Tortoises of the genus *Homopus*.—A communication was read from Mr. W. L. Sclater, containing a series of critical notes on the Indian species of the family Muridæ.—A communication was read from Mr. J. T. Cunningham, containing some notes on the secondary sexual characters of the genus *Arnoglossus*. The author showed that the so-called *Arnoglossus laterna* is only the female of *A. lophotes*.—Mr. R. Bowdler Sharpe read the sixth part of his series of notes on the Hume Collection of Birds. The present communication treated of the Coraciidæ of the Indian region, and contained descriptions of three new species.—A communication was read from Miss E. M. Sharpe, containing an account of a collection of Lepidoptera made by Mr. Edmund Reynolds on the rivers Tocantins and Araguaya, and in the province of Goyaz, Brazil.—Mr. Edmund S. Hall gave an account of the occurrence of a persistent right posterior cardinal vein in a Rabbit.—This meeting closes the present session. The next session (1890–91) will commence in November 1890.

Paris.

Academy of Sciences, June 23.—M. Hermite in the chair.—On the partial eclipse of the sun on June 17, by M. J. Janssen.—Theory of the motion of fluids near to the wide opening of a delivery pipe, where the liquid threads have not acquired their normal inequalities of velocity, by M. J. Boussinesq.—Comparison of the theoretical figure of a storm given in the *Comptes rendus* of June 9 with the facts known to navigators, by M. H. Faye.—The work and progress of the Arago Laboratory in 1890, by M. de Lacaze-Duthiers.—On the visible and photographic spectrum of the great nebula of Orion, by Dr. W. Huggins.—On the distribution of *Salmo quinnat* on the Mediterranean coasts of the south-east of France, by MM. A. F. Marion and F. Guitel.—On the glycolytic power of blood and of chyle, by MM. R. Lépine and Barral.—Observations of Brooks's comet (March 19, 1890) made at Bordeaux Observatory, by MM. G. Rayet, Picart, and Courty. Observations of position are given extending from May 19 to June 20, being in continuation of those published in the *Comptes rendus* of March 31, April 8, and May 19.—Elements and ephemeris of the new minor planet (293) discovered at Nice Observatory on May 20, by M. Charlois.—Partial eclipse of the sun of June 17, in the morning, observed at Nice, by M. Perrotin.—Observation of the eclipse of the sun of June 16–17, made with the Brunner equatorial of Lyons Observatory, by M. Gonnessiat.—On the partial eclipse of June 16–17 (Algiers Observatory), by M. Ch. Trépied.—The solar eclipse of June 17, by M. E. L. Trouvelot. (For eclipse observations see Our Astronomical Column.)—On the international zero of altitude, by M. Ch. Lallemand.—On a direct-reading dynamometer, by M. G. Trouvé.—Reciprocal action of alkaline haloid salts and mercurous salts, by M. A. Ditte.—On some phosphates of lithium, beryllium, lead, and uranium, by M. L. Ouvrard. A number of double phosphates formed by the action of molten alkaline phosphates upon the carbonates of lithium and glucinum and the oxides of lead and uranium are described; among them occurs a double phosphate of beryllium and sodium corresponding in composition with the recently discovered mineral beryllonite.—Combinations of double chlorides of phosphorus and iridium with arsenious chloride, by M. G. Geisenheimer. By heating the constituents in a sealed tube to 250°, ruby-red prismatic crystals of $2(Ir_2P_3Cl_{15}).5AsCl_3$ are formed.—On the sub-fluoride of silver, by M. Guntz. The existence of a sub-fluoride of silver was indicated by the analyses of a precipitate produced on the negative pole when subjecting a hot saturated solution of silver fluoride to electrolysis, employing a very strong current and silver electrodes. The pure salt is obtained in quantity by heating finely divided silver with a saturated solution of silver fluoride on a bath to a temperature of from 50°–90°. Analyses of the product prove it to be the sub-fluoride of silver Ag_2F.—A contribution to the study of ptomaïnes, by M. Œchsner de Coninck.—On the preparation of wine ferments, by M. A. Rommier.—On the sense of smell in star-fishes, by M. Prouho. The author concludes that star-fishes excited by the presence of a bait are guided by sensations perceived by the extremities of their arms. The sense of smell is not diffuse in star-fishes, but is localized in the limbs useless for locomotion at the back of the ocellary plate.—The photographic registration of the chlorophyll function by the living plant, by M. Timiriazeff.—On the hypersthene andesites and labradorites of Guadaloupe, by M. A. Lacroix.—On the vertical circulation in the deep ocean, by M. J. Thoulet.

LIFE OF SEDGWICK.[1]

II.

The Life and Letters of the Reverend Adam Sedgwick, LL.D., D.C.L., F.R.S., Fellow of Trinity College, Cambridge, Prebendary of Norwich, Woodwardian Professor of Geology, 1818-73. By John Willis Clark, M.A., F.S.A., and Thomas McKenny Hughes, M.A., F.R.S. Two Volumes. (Cambridge: University Press, 1890.)

THE main results of Sedgwick's geological work, as stated in these volumes, are briefly as follows. Passing over several contributions, often of permanent value, to the geology of the crystalline rocks of Cornwall and of the Carboniferous' system, especially in the north of England, we come first to his monograph on the Magnesian Limestone and lower portion of the New Red Sandstone series. Of this Prof. Hughes justly says: "It is at once broad and minute: broad in its generalizations—for it places in order a complex group of rocks, which, until it was written, were in complete confusion; and minute in working out, through the whole of the district selected, from Nottingham to the southern extremity of Northumberland, the boundaries of the different formations and their relations to each other." We are not, however, prepared to follow Prof. Hughes, if we understand him rightly, in his objection to the name Permian as designating the lower part of this series, for the break between that formation and the so-called Trias is probably more important than at first sight appears, and New Red Sandstone is a name obviously provisional.

Sedgwick undertook a task of unusual difficulty in investigating the rock masses which enter into the "Cumbrian mountains," and ascertaining their relations with the strata in adjacent regions, but it was so successfully accomplished that subsequent observers have made few if any important changes, though of course they have amplified many details, in his results.

His work also among the Palæozoic rocks in Devonshire and Cornwall, in which, after a time, he was joined by Murchison, was a long and arduous task, at first productive of much controversy. In this, others, as it is said, "helped with facts or with useful criticism," but it seems a fair statement of the result to say that "the now received classification of the Devon rocks remains as Sedgwick and Murchison left it: Culm measures (Carboniferous) above and Devonian below; the base of the Devonian being there unknown."

Sedgwick's work in Wales commenced in the year 1831. It was a task from which the boldest geologist might well have recoiled. The country was comparatively difficult of access, the maps were not good, little help was to be obtained from palæontology; the "greywacke" rocks were a vast *terra incognita*. But the "stiffer" the problem, the greater its attraction for Sedgwick. In that and the following years he unravelled the complicated structure of North Wales, and placed in order the great rock masses, from the base which he established in the neighbourhood of the Menai Straits, under the great group named after the town of Harlech, to the top of that which he called the Bala group, clearly distinguishing the latter from the Denbigh Grits and other rocks, which are now universally recognized as Silurian. Of this part of Sedgwick's work, Prof. Hughes gives a lucid history, of which the following is a brief outline.

Sedgwick spent the summer of 1831 in North Wales, and established the succession of the rocks from his base line upwards, across Snowdon and the Merionethshire axis. Short accounts of his results were laid before the Cambridge Philosophical Society and the British Association in June 1832. Next month he sent from Wales sections which illustrate the stratigraphical succession from the Menai Straits to the Berwyns. Thus, to quote Prof. Hughes's words:—

> "Sedgwick, by 1832, had explained the geological structure of North Wales; had sketched out the leading subdivisions of the Cambrian rocks, and had established the correct sequence of the Arenig and Bala series, and placed them in true relation with what were afterwards known as the Silurian (Upper Silurian of Murchison) in Central Wales and the borders."

Later in the autumn of this year we find that he "had ascertained the exact position of the Wenlock limestone south of Llandovery," and drawn a rough section, "correct as far as it goes," from the Lower Bala beds, in the valley of the Towy, to the Old Red Sandstone. Further communications, as the result of this prolonged labour in the field, were laid before the British Association and the Cambridge Philosophical Society in 1834. From time to time during the next twelve years important details were worked out; perhaps the most marked advance being made in the difficult region of Central Wales, between the Towy and the sea, where Sedgwick succeeded in establishing the general succession of the strata, obscure and almost unfossiliferous as they are. In 1851 he practically proved that the name Caradoc which had been used by Murchison in "The Silurian System" (published in 1839, from work begun in 1831) must cover two distinct groups, one containing Bala fossils, the other clearly underlying the Wenlock group, with fossils similar to those in the latter, but without those characteristic of the former. This is actually demonstrated in a paper published in 1852.

Soon afterwards began, at any rate openly, the difference regarding the limits of the Cambrian and Silurian systems which unhappily estranged him from his friend and from the Geological Society. The immediate cause appears to have been the publication, by the Geological Survey, of a map of North Wales, on which the colours used to distinguish Silurian rocks were extended over a large part of those hitherto described by Sedgwick as Cambrian. Why this was done, it is now difficult to understand. Between the base of the Cambrian and that of the Old Red only one well-marked physical break exists—that at the base of the May Hill Sandstone (Upper Llandovery). Below this is only a palæontological break, which at that date had not been clearly recognized. Accordingly,

[1] Continued from p. 219.

as time went on, the lower limit of the Silurian system descended, like a stone sinking in the mire, till at last "Lower Silurian" actually included the Menevian rocks, as may be seen to this day at the Museum in Jermyn Street. This being so, one would have thought that, even if Murchison had preceded Sedgwick in the publication of the results of his work—which was not the case—the two vital errors in his reading of the beds between the base of the Wenlock and that of the Arenig ought to have deprived him of any claim on account of prior nomenclature. Sedgwick had placed the beds of his Cambrian system in right order from base to top—that is, to beneath the so-called Upper Llandovery. These facts appear to be fully proved, and thus Sedgwick had good cause to feel aggrieved. Into the more personal aspect of the controversy it is needless to enter. One cannot greatly wonder that when once a rift opened in the lute it quickly became a rent, for the two men were so unlike, both in their excellencies and their defects. Nor can it be denied that Murchison had his grievances. Sedgwick was vexatious as a coadjutor in the preparation of papers, for he was unpunctual and unready; he was also slow in duly publishing the results of his own labours, contenting himself too much with informal communications to the British Association and the Cambridge Philosophical Society, instead of laying carefully written memoirs before the Geological Society. But it must be remembered that his time was much occupied. His fellowship, his professorship, his prebend—all entailed duties which were often heavy; and Sedgwick was too honourable a man not to give "a full pennyworth" to those who bought from him. He had to work to live, for he had no private means. It cannot, however, be denied that he interpreted too literally the precept, "Whatsoever thy hand findeth to do, do it with all thy might." Social engagements, political contests, University disputes, too often turned his attention from the main work of his life, and gave some ground for Lyell's severe remark:—"He has not the application necessary to make his splendid abilities tell in a work. Besides, everyone leads him astray; . . . to become great in science, a man must be nearly as devoted as a lawyer, and must have more than mere talent." Still it must be remembered that Sedgwick's health, notwithstanding the great age to which he attained, was far from good, and his constitutional ills were those which make continued sedentary work extremely trying. He was also unlucky in the way of accidents: a dislocated wrist, a broken arm, bad falls, an eye permanently injured, make up a large catalogue of damages for a Cambridge Professor.

Still, although I take Prof. Hughes's view as to the rights of the case, I cannot, under existing circumstances, agree with his condemnation of the proposal to give a new name —Ordovician—to the beds between the base of the May Hill Sandstone and that of the Arenig. "One shell is given to Sedgwick, another to Murchison, but who gets the oyster?" A smart remark, doubtless, but like many such rather misleading. There is no question of shell or oyster in the matter. Each part is equally edible—or indigestible. Granted that Sedgwick has the better title, possession, in questions where the right is not wholly on one side, counts for something with practical men. Cambrian also, as defined by Sedgwick, is rather disproportionately large, and the palæontological break beneath the Arenig is more marked than that which severs the Cambrian from the Silurian. I venture to think that, apart from personal questions, a tripartite division would be pronounced most in accordance with the principles of geological classification, and should not be surprised, if this be repudiated by Sedgwick's defenders, at the ultimate disappearance of Cambrian in the omnivorous maw of Silurian.

Sedgwick's permanent estrangement from the Geological Society I venture to think a mistake. Doubtless he had good cause for indignation at his treatment by its Council, and the well-meant, but arbitrary, action of one of its officers. But a Council is only a temporary aggregate of individuals, and the offence after a time should have been condoned. Its members did not really understand the question at issue; they were evidently actuated, not by any desire to be unjust, but by a nervous anxiety to keep the peace, and forgot, as men so often do, that when a sore is hidden under a plaster, it commonly festers. So the event proved in this case: molluscous amiability met with its usual reward. If the combatants had "fought it out," fairly and honourably, there would have been more chance of an ultimate reconciliation.

These interesting volumes enable us better than ever to estimate Sedgwick's place among the geologists of his generation. His especial strength lay in stratigraphy. In his power of unravelling a complicated district by attention mainly to physical evidence he has never been equalled. He was a patient and unwearied collector of facts, with a wholesome dread of viewing them "through the distorting medium of an hypothesis." Yet it must be admitted that his judgment was often warped by prejudice, using the word in its technical sense. His great power is best displayed when he attacks a problem which is completely novel; for, reformer though he was in politics, his mind, in scientific matters, had a distinctly "conservative" bias, and was too much influenced by ideas which had no better authority than tradition. Of this defect the book records several instances. It will suffice to mention his opposition to Lyell's "Principles of Geology" and to Darwin's "Origin of Species." It is of course possible to overstate the doctrine of uniformity and misuse the hypothesis of evolution; but the progress of knowledge has not justified Sedgwick's attacks on the main arguments of these works, and it must be admitted that he was inferior to their authors in power of inductive generalization. Perhaps no better example could be found of Sedgwick's strength and weakness than his well-known paper "On the Structure of Large Mineral Masses," where a magnificent co-ordination of facts has a somewhat disappointing conclusion.

But even if we grant defects in the geologist as in the man, it is impossible to deny his real greatness. Those who loved Sedgwick as a friend are fast becoming few; but the number of those who reverence his memory as that of a master in science is likely to increase rather than to diminish as his work is weighed in the balance and tested by time. To myself, though I did not know him in his prime, he always appeared to be not only truly noble in spirit, but also illuminated with that divine fire which distinguishes the man of genius from the man of talent.

T. G. Bonney.

MEASLES AND STRAW-FUNGI.

The Prevention of Measles. By C. Candler. (Melbourne, Victoria. London: Kegan Paul, Trench, and Co., 1889.)

NOTWITHSTANDING the amount of labour which Mr. Candler has expended upon this work, and the ingenuity of some of his hypotheses, we cannot but think that his method might almost be taken as an example of how an inquiry of this kind ought not to be conducted. The author starts with an account of the observations of Dr. Salisbury, an American physician, published in 1862, by which he claimed to have established that a disease called "camp measles," prevalent among American soldiers, was produced by infection with certain fungi derived from musty straw. Salisbury cautiously abstained from positively asserting that the disease was identical with common measles, but said he could see no difference between them; and that an attack of the former protected from the latter. If the diseases were identical, his explanation applied to common measles.

This hypothesis of Dr. Salisbury's was very carefully examined by Dr. J. J. Woodward, Dr. Pepper, and others, who came, by experiment and reasoning, to the conclusion that Dr. Salisbury had not proved his point; and the theory that straw-fungi are the cause of measles has been generally discredited.

Mr. Candler thinks that the refutation of Dr. Salisbury's theory was not complete; and, falling into the not uncommon fallacy that "not absolutely disproved" is equivalent to "proved," he treats it as if it were certainly established, and proceeds to build further hypotheses upon it.

This we consider to be an inversion of the right method of procedure in science. Supposing that Salisbury's results suggested matter for further inquiry, the proper way to begin would be by testing their soundness. If Mr. Candler had himself repeated, or got some scientific friend to repeat, Salisbury's experiments with mouldy straw derived from a place where measles was rife, he might have obtained results, either positive or negative, of great value; and would certainly have made a more important contribution to the subject than is contained in the present volume.

Mr. Candler further extends the straw-fungus theory by supposing that the fungi become changed into bacteria in the body; and, indeed, uses Salisbury's untested and unrepeated experiments as a proof of one of the most fundamental questions (if it be a question) of biology—namely, the alleged genetic relation of fungi and bacteria.

The author's argument is so characteristic of his book that we venture to state it formally thus. Salisbury, by injecting fungus-dust from mouldy straw into himself and others, produced a disease resembling measles. But all such diseases are produced by "pathophytes," *i.e.* bacteria. Therefore Salisbury "*caused pathophytes to develop from fungi*" (the italics are the author's) "and demonstrated that cardinal point in dispute in regard to the bacteria."

An easy solution indeed! if, at least, it were proved that the dust of mouldy straw contained no bacteria (though such are pretty certain to be present), and if it were proved also that fungi by themselves cannot produce specific diseases (though some such diseases are well known in the lower animals, and are not quite unknown in man).

But even granting these points, surely the experiment might be repeated at least once before it is made a corner-stone of cryptogamic botany!

The dangerous fungus of measles Mr. Candler believes to lurk in damp and mouldy straw palliasses; and rejecting altogether the idea of contagion, he believes that measles is entirely due to the use of straw bedding imperfectly aired. Towards the end of the book the author begins to tread on firmer ground than at the beginning, for he bases his conclusions on some induction from facts.

In the great epidemic of measles in Victoria in the years 1874-75, he affirms that he could not discover any instance of measles in a dwelling from which damp straw (in the form of bedding) had been excluded, but in every house where measles occurred, the presence of damp straw in the bed-rooms was easily made out. Some curious instances of exemption, especially in the case of public institutions, such as asylums and the like, are quoted, and we seem to be on the verge of a systematic collation of evidence. But the result is disappointing, as the enumeration of instances is altogether inadequate to establish a general law. It is strange that Mr. Candler makes so much of the exemption of lunatic asylums from measles, to account for which he has recourse to elaborate explanations of the use of straw bedding. Surely the exemption of persons shut up in asylums, prisons, &c., from contagious epidemic diseases, is a very familiar fact, and easily explained. Such persons receive few visitors, and what is to the point here, lunatics especially are seldom or never visited by children, who are the chief carriers of the measles-contagium. Nor can we say that the author is more successful in explaining on his theory the great epidemics of measles in Fiji and in Japan.

Mr. Candler's book is written with much earnestness, not without candour, and contains many curious facts, though it fails to prove its main contention. There is nothing impossible in the supposition that damp straw favours the growth of "microbes"; and it might conceivably be proved by sufficient evidence that this is a favouring or even a necessary condition for the growth of the specific virus of measles. The objection is that the evidence is quite inadequate. Moreover, were such a law established, it would by no means prove that the cause of measles was a fungus, since it might just as well be a bacterium or other living thing.

In the meantime it cannot do harm and may do much good to draw attention to the insanitary consequences which may follow the use of straw bedding. A straw palliasse unchanged and undisturbed for years is not a desirable article of furniture, and housekeepers will do well to turn such things out of their bed-rooms. Fortunately, in this country they are being rapidly superseded by steel mattresses; and on inquiry at the large furnishing houses we find that few palliasses are now sold. We shall see whether measles becomes thereby extinct.

J. F. P.

SPIDERS' WEBS.

American Spiders and their Spinning Work: a Natural History of the Orb-weaving Spiders of the United States, with Special Regard to their Industry and Habits. By Harvey C. McCook, D.D. Vol. I., pp. 1-372, and 353 Woodcut Figures. (Philadelphia: Allen Lane and Scott, 1889.)

ALTHOUGH much has been written in a more or less fragmentary way by various authors, on the spinning organs and geometric snares of spiders, as well as on the method of entrapping their prey, the present volume is the first in which all that has been before touched upon is brought together in any systematic manner. Two other volumes are intended to follow, but the one under notice completes the subject of geometric web-spinning. In Vol. II. it is purposed to deal with the habits and industry of spiders, associated with mating, maternal instincts, the life of the young, distribution of species, and other general habits; while in the third (and concluding) volume the whole of the geometric spiders—"orb-weavers"—of the United States will be treated of systematically, and illustrated by numerous coloured plates. It might have been thought that Vol. III. would have more naturally preceded the other two; but perhaps it is scarcely fair to criticize too closely the form in which an author chooses to present his subject. Dr. McCook's evident aim is to popularize the subject of spiders' web-spinning, and all that relates to it. This is shown not only by the way in which the subject is presented, but by the bestowal of English trivial names at every turn; though it may well be doubted how far science is really advanced by thus cumbering its nomenclature. Among the most interesting portions of the present volume are those in which some snares are described, combining the geometric or *Epeirid* type with that of the *Theridiidæ*, and of which no examples have yet been found in Great Britain. Space, however, forbids our going into details of these, nor, in fact, of any part of the work. The whole volume is a mass of details, evidently the result of careful and long-continued observations; and made patent not only to the mind by lucid description, but to the eye by the very graphic illustrations thickly scattered over its pages. On one point, of very great interest in the making of geometric snares—the formation of the portion studded with viscid globules—Dr. McCook approaches very nearly to a solution of the method by which these globules are placed on the lines, but the method[1] itself appears to have as yet escaped observation.

Dr. McCook tells us that his first intention was "to write a natural history of all American spiders," but no one who has gone even a little into the spider fauna of that large region will wonder that, when this intention came really to be grappled with, the plan changed; and probably those interested in the study of spiders have gained by the exchange. The work done in this volume is divided into seven parts. Part I. treats of the general classification and structure of spiders and their spinning organs; Part II. of the general characteristics, construction, and armature of webs; Part III. is on characteristic forms and variations of snares; Part IV. on certain geometric webs devoid of viscid globules, and on "spring snares"—those singular arrangements in which the spider holds the snare taut by a single line with the slack gathered up in its claws, and, on an insect striking the web, suddenly lets the slack go with a spring, to the more certain entanglement of the prey. In Part V. we have a detail of many curious facts bearing upon the skill and intelligence of spiders, and also as to the mechanical strength of their webs and their physical powers; but some of the most curious of these details, in regard to the "engineering skill" of spiders are, no doubt rightly, set aside by the author, so far, at least, as their bearing on such skill is concerned. Part VI., under the head of "Provision for Nurture and Defence," treats of the methods of using their snares in procuring food, and on the effects and uses of the poison secreted in the falces of spiders; and the volume concludes with Part VII., in which the "nesting habits" of geometric spiders are gone into, as also the origin, use, and development of nest-making in various tribes of spiders; and the "genesis of snares," under which last head the author gives us his views as to the steps by which a simple line may have become the complicated snares now formed by these spiders.

The volume thus completed is well got up, and, abounding in interest from beginning to end, may well stir up in everyone to whom spiders are not (and it is to be regretted they sometimes are) objects of abhorrence, a wish for the speedy appearance of the remainder of the work, Vols. II. and III., the proposed contents of which have been noticed above. O. P. C.

NATIONAL HEALTH.

National Health. By B. W. Richardson, M.D., F.R.S. Abridged from the "Health of Nations," of Sir Edwin Chadwick, K.C.B. (London: Longmans, Green, and Co., 1890.)

THE aim of this work is sufficiently explained in the preface, in which the editor states that his object has been to condense, without comment, into a single handy and cheap volume, the most practical and most popular parts of Sir Edwin Chadwick's "Health of Nations."

The volume opens with a biographical sketch of the author of the larger work, giving an interesting and detailed account of his important life-work in public health and sanitation; the remainder of the work being divided up into four sections, dealing respectively with health in the dwelling-house, in the school, the health of the community, and health in the future.

The first section, relating mainly to the dwellings of the working classes, is devoted to an inquiry into the serious consequences to health of unsanitary surroundings, such as overcrowding, want of ventilation, deficient water-supply, and imperfect drainage, especially when, as is often the case in houses of the poorer classes, the walls are pervious and absorbent through faulty construction and the use of bad materials. The author points out that as good house-drainage and complete sanitary work has proceeded in old houses, low health has immediately improved; a similar improvement becoming visible at the same time in the moral as well as the physical con-

dition of the people. A number of pages are taken up with a description of an ideal water-supply and methods of drainage, great stress being laid on the necessity for laying down drains and sewers of the smallest possible size consistent with the immediate removal of the maximum flow at any one time. The wisdom of such a plan is now admitted on all hands, the powerful flow preventing all deposit, and by maintaining a down draught from the houses, avoiding the ingress of sewer-gas.

In the section on "Health in the School," we find an account of the "Half-time System" initiated by Sir E. Chadwick with the object of ensuring to children employed in manufactories a certain time for school-work and recreation, in addition to that devoted to physica labour. The time which should be occupied by lessons at various ages, and the effect of good lighting, warming, ventilation, and personal cleanliness in augmenting the receptivity of pupils, are ably discussed, and the value of military drill as a part of the education is rightly insisted on. The methods for the prevention of the occurrence and spread of epidemics are so briefly touched upon that we cannot but think that the importance of the subject might have demanded somewhat fuller treatment.

The most important portion of the following section deals with the results of occupation and surroundings on the length of life in various classes of society, the effects of intemperance and of bad feeding being specially considered; the author, however, being careful to point out the sources of fallacy to which all such statistics are liable. The last portion of the book is mainly devoted to an attack on the Malthusian theory.

The work is not, and does not in any way pretend to be, a student's text-book, so that the candidate for a diploma in public health will hardly find it of much value, except, perhaps, from an historical point of view. Still, there is much in its pages which may be studied with advantage by those interested in matters pertaining to general hygiene, especially as it presents in moderate compass a most readable account of the labours of a distinguished pioneer in the field of sanitary science.

OUR BOOK SHELF.

Induction and Deduction, and other Essays. By Constance C. W. Naden. Edited by R. Lewins, M.D. (London: Bickers and Son, 1890.)

THIS little work acquires a melancholy interest from the fact that the talented young authoress has not lived to see its publication. The title essay, on "Induction and Deduction," gained in 1887 the Heslop Memorial Medal, provided out of the proceeds of a bequest to the Mason Science College of Birmingham by the late Dr. Heslop, and awarded annually by the Council of the College. It is clear, concise, well-arranged, and carefully thought out; and leads one to believe that, had the hand of Death been withheld, Miss Naden would have made valuable contributions to philosophic thought. For Miss Naden the fundamental principle in philosophy is the famous Protagorean formula of relativity, that "Man is the measure of all things, of things that are that they are, of things that are not that they are not." She insists on the close inter-connection of induction and deduction in all reasoning, the two processes not being antagonistic but complementary. Both involve cognition and recognition; but whereas induction is a process of cognition involving recognitions, deduction is a process of recognition involving cognitions. The historical development is traced from the Greek cosmologists, through Plato, Aristotle, Bacon, Descartes and Locke, Mill, Jevons, and J. H. Green; and there are many signs that Miss Naden had not merely grasped but assimilated the teachings of those whose influence on the theory of reasoning she traced.

That Miss Naden was not wanting in humour is seen from the "Legend of the Inductive Method" in her introduction. This is so good as to be worth quoting.

"In the beginning was a set of philosophers, who, instead of looking about them, simply investigated their own thoughts, and tumbled into many ditches, not so much through star-gazing, as through mind-gazing. Out of their inner consciousness they extracted a great many principles which were inapplicable to Nature, and were therefore of none effect; and on account of this wilful perversion they failed to invent the steam-engine or to discover the circulation of the blood. This state of things went on for a long time; and in the Middle Ages matters grew worse rather than better; for now there appeared a set of men called schoolmen, who submitted everything to the authority of the Church and of Aristotle, and wasted their time in frivolous debates about phantoms named quiddities and hocceities and haeceities. Their method also was deductive, and was false. But in the glorious sixteenth century, and in our own glorious island, there arose a Lord Chancellor who wrote a book which changed the face of the intellectual world. This great man found out that the proper office of the mind is to make discoveries, and that the proper way to make discoveries is to interrogate Nature. He laid down rules for the correct framing of our interrogations. He is the father of all such as make far places near by steam-engines and electric telegraphs, or numb our pain by anæsthetics, or light the world by gas or electricity. His method is called inductive, and is true."

The other essays are on ethical and sociological questions, and on "Hylo-Idealism: the Creed of the Coming Day." They are somewhat unequal in value. The work is prefaced by a short memoir. C. LL. M.

The Lepidopterous Fauna of Lancashire and Cheshire. By John W. Ellis, M.B. (Vic.), F.E.S. (Leeds: Printed by McCorquodale and Co., 1890.)

THIS volume, the contents of which are reprinted from the *Naturalist*, will be of great service to all students of the subject to which it relates. Dr. Ellis does not offer his list as conclusive; but he has "endeavoured to present, as completely as possible, the facts known with reference to the occurence in Lancashire and Cheshire of the British species of Lepidoptera." The list is preceded by a short statement as to the geological and meteorological conditions which, by affecting the flora of the district, affect indirectly its lepidopterous fauna.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Intelligence of Chimpanzees.

ONE is glad to see that your review of Mr. Stanley's book calls attention to the following statement, which is made on the authority of Emin Pasha, and rendered in his own words:—

"The forest of Msongma is infested with a large tribe of chimpanzees. In summer-time, at night, they frequently visit the plantations of Mswa Station to steal the fruit. But what is remarkable about this is the fact that they use torches to light the way! Had I not witnessed this extraordinary spectacle personally, I should never have credited that any of the Simians understood the art of making fire."

On this passage your reviewer remarks:—"We cannot doubt

the accuracy of Mr. Stanley's report, nor the trustworthiness of Emin's observation; but we should like to have more details." But as Emin himself allows that he would never have credited the fact alleged had he not witnessed it personally, we may, perhaps, without discourtesy, refuse to accept so bald a statement of "this extraordinary spectacle." Of what were the torches constructed? How do these "Simians" practise "the art of making fire"? Having once acquired the art, do they use it only for the purpose of making "torches to light the way"?

Speaking for myself, and not without some knowledge of the intelligence of a chimpanzee, I confess that, until at least these "details" are supplied, I *do* "doubt the trustworthiness of Emin's observation," and I shall be satisfied to suppose that, owing to a shortsightedness of which we have heard so much, the Pasha has mistaken a band of native children for his "large tribe of chimpanzees." GEORGE J. ROMANES.

July 6.

Dr. Kœnig's Theory of Beats.

I MADE an experiment, some years ago, which would seem to support and illustrate Dr. Kœnig's theory of beats, as set forth by Prof. Silvanus Thompson in his lecture before the Physical Society, and reported in your issue of June 19. Taking two tuning-forks, each of which gave the middle C (256 vibrations), I weighted one of them so as to make it give one beat a second when sounded with the other. Then, sounding this fork, so weighted, with another giving the fifth above, G (384 vibrations), I heard distinctly three beats a second. I could only account for these beats by assuming that the weighted fork C produced a feeble twelfth, and that the fork G produced a feeble octave. These two overtones would, if present, give three beats a second, $255 \times 3 = 765$, and $384 \times 2 = 768$. But I could not show by any independent evidence that these overtones are really present when the tuning-forks are sounded; and, in fact, the general opinion is against such an assumption.

If, however, Dr. Kœnig's theory be accepted, the beats are easily accounted for. According to his view, as stated by Prof. Thompson, these forks when sounded together would yield two sets of beats, called, respectively, *superior* and *inferior*; and each set of beats would blend into a musical tone. Thus we should get—

Inferior beat ... ... $384 - 255 = 129$
Superior beat ... ... $510 - 384 = 126$

These primary beats, or beat-tones as they may be called, of 129 and 126 vibrations would act as independent tones, and produce secondary beats of three in the second.

I hope Prof. Thompson's paper will be published in full, that we may all have an opportunity of considering the details of Dr. Kœnig's reasoning; but, in the meantime, I thought the experiment I have described would be interesting to your readers, as it is very easily made. Perhaps I should add that the experiment succeeds equally whether the forks are mounted on resonance-boxes or not; and therefore the effect cannot be ascribed to the boxes. GERALD MOLLOY.

Catholic University, Dublin, June 22.

The "Night-shining Clouds."

I HAVE not yet seen, in any English publication, mention of the important results of the more recent researches of Herr O. Jesse and his coadjutors on these clouds. By taking simultaneous photographs from two or more widely separated places, the height of the clouds has been determined with great exactness. On July 2, 1889, this was found to be somewhat over 80 kilometres. The operations have evidently been conducted with great care, and the results may therefore be fully trusted. The question is therefore set at rest as to whether the clouds are self-luminous, for it is evident that at such a height their brightness is fully accounted for by the sun shining upon them. In 1886, Herr Jesse had, upon this supposition, ascertained their brightness to be from 49 to 54 kilometres, and that the lower the sun descended the smaller was the illumination needed to show them as the atmosphere darkened, so that the calculated height increased with the sun's depression below the horizon. Some people were incredulous about the great height at that time attributed; but the photographs give them a yet greater elevation, which places them quite out of the category of any ordinary clouds. Those who have not seen the photographs may query as to the possibility of identifying the same points in the two photographs compared, and may think that even synchronous photographs might show very different details by being taken from two distant stations; but, on the contrary, in those examples I have seen, the two photographs are so exactly alike that it is very difficult to discover any difference whatever between them, though taken at Nauen and Steglitz, 35 kilometres apart, which consideration of itself shows the enormous height of the clouds. In some of the photographs the stars α and β Aurigæ are distinctly visible.

The letter by "M. E." (p. 198) evidently describes an apparition of these clouds on the night of the 17th ult., when, as I am informed, they were also seen from Sunderland; but I have not myself seen them either this year or last, though they have been seen both years in Germany—more especially after midnight. They generally are seen in June and July, the earliest recorded date being May 26, and the latest August 11.

Sunderland, July 8. T. W. BACKHOUSE.

IN a letter which you published some time ago on "night-shining clouds," there was a request for notes of their occurrence. It may, therefore, interest some of your readers to know that they were well seen here on the evening of the 4th inst. They appeared rather suddenly shortly before 10 p.m., covering the sky from N. to N.E., and from the horizon for about 15° up. They were not in regular strata, but scattered in all directions, like cirrus after a storm. About midnight they were still visible, but more to the left, some being west of north. The first time I saw these clouds was on June 18, 1886, soon after midnight, when they were about N.W., and 20° from the horizon, and since then they have often been seen; but never, so far as I know, with the storm-tossed appearance they presented last week. CECIL SHAW.

Belfast, July 7.

A VERY fine display of luminous night-clouds was visible here during the night of the 4th inst., the luminosity extending to an altitude of 30° above the northern horizon, ending above in definite cirrous streamers, or cloud wisps. It will be seen by the Ben Nevis June Summary that these clouds were noted on the 29th ult. In NATURE of the 3rd inst. (p. 222), the writer's communication on this subject was misprinted Kensington instead of Kingstown (Co. Dublin). The present dates from Scotland.

Aberdeen, July 7. D. J. ROWAN.

An Electrical Effect.

IT may be of value to remind teachers of an effect not generally known, which is produced by varying the ordinary mode of performing the experiment of putting pieces of zinc and silver in the mouth and touching them, to obtain the acid taste which accompanies the completion of the electric circuit.

If the piece of zinc be placed under the tongue, and a florin vertically between the upper lip and the top row of teeth, and the two metals be brought in contact, a faint flash is seen in both eyes when the eyes are open.

If the eyes are shut the sensation of light is not felt, so that the effect is probably due to a muscular twitching.

It is necessary to use a large silver coin, and not a shilling, and to push it well home behind the upper lip.

The experiment so made seems to be a handy and simple illustration of the meaning of subjective phenomena.

Clifton College, July 7. EDWARD B. COOK.

THE PHOTOGRAPHIC IMAGE.[1]

THE history of a discovery which has been developed to such a remarkable degree of perfection as photography has naturally been a fruitful source of discussion among those who interest themselves in tracing the progress of science. It is only my presence in this lecture theatre, in which the first public discourse on photography was given by Thomas Wedgwood at the beginning of the century, that justifies my treading once again a path which has already been so thoroughly well beaten. If any further justification for trespassing upon the ground of the historian is needed, it will be found in the circumstance that in the autumn of last year there was held a celebration

[1] Friday Evening Lecture delivered at the Royal Institution by Prof. Raphael Meldola, F.R.S., on May 16, 1890.

of what was generally regarded as the jubilee of the discovery. This celebration was considered by many to have reference to the public disclosure of the Daguerreotype process, made through the mouth of Arago to the French Academy of Sciences on August 10, 1839. There is no doubt that the introduction of this process marked a distinct epoch in the history of the art, and gave a great impetus to its subsequent development. But, while giving full recognition to the value of the discovery of Daguerre, we must not allow the work of his predecessors and contemporaries in the same field to sink into oblivion. After the lapse of half a century we are in a better position to consider fairly the influence of the work of different investigators upon modern photographic processes.

I have not the least desire on the present occasion to raise the ghosts of dead controversies. In fact, the history of the discovery of photography is one of those subjects which can be dealt with in various ways, according to the meaning assigned to the term. There is ample scope for the display of what Mr. Herbert Spencer calls the "bias of patriotism." If the word "photography" be interpreted literally as writing or inscribing by light without any reference to the subsequent permanence of the inscription, then the person who first intentionally caused a design to be imprinted by light upon a photo-sensitive compound must be regarded as the first photographer. According to Dr. Eder, of Vienna, we must place this experiment to the credit of Johann Heinrich Schulze, the son of a German tailor, who was born in the Duchy of Madgeburg, in Prussia, in 1687, and who died in 1744, after a life of extraordinary activity as a linguist, theologian, physician, and philosopher. In the year 1727, when experimenting on the subject of phosphorescence, Schulze observed that by pouring nitric acid, in which some silver had previously been dissolved, on to chalk, the undissolved earthy residue had acquired the property of darkening on exposure to light. This effect was shown to be due to light, and not to heat. By pasting words cut out in paper on the side of the bottle containing his precipitate, Schulze obtained copies of the letters on the silvered chalk. The German philosopher certainly produced what might be called a temporary photogram. Whatever value is attached to this observation in the development of modern photography, it must be conceded that a considerable advance was made by spreading the sensitive compound over a surface instead of using it in mass. It is hardly necessary to remind you here that such an advance was made by Wedgwood and Davy in 1802.[1] The impressions produced by these last experimenters were, unfortunately, of no more permanence than those obtained by Schulze three-quarters of a century before them.

It will perhaps be safer for the historian of this art to restrict the term photograph to such impressions as are possessed of permanence: I do not, of course, mean absolute permanence, but ordinary durability in the common-sense acceptation of the term. From this point of view the first real photographs, *i.e.* permanent impressions of the camera picture, were obtained on bitumen films by Joseph Nicéphore Niepce, of Châlons-sur-Saône, who, after about twenty years' work at the subject, had perfected his discovery by 1826. Then came the days of silver salts again, when Daguerre, who commenced work in 1824, entered into a partnership with Niepce in 1829, which was brought to a termination by the death of the latter in 1833. The partnership was renewed between Daguerre and Niepce de St. Victor, nephew of the elder Niepce. The method of fixing the camera picture on a film of silver iodide on a silvered copper plate—the process justly associated with the name of Daguerre—was ripe for disclosure by 1838, and was actually made known in 1839.

The impartial historian of photography who examines critically into the evidence will find that quite indepently of the French pioneers, experiments on the use of silver salts had been going on in this country, and photographs, in the true sense, had been produced almost simultaneously with the announcement of the Daguerreotype process by two Englishmen whose names are as household words in the ranks of science. I refer to William Henry Fox Talbot and Sir John Herschel. Fox Talbot commenced experimenting with silver salts on paper in 1834, and the following year he succeeded in imprinting the camera picture on paper coated with the chloride. In January 1839 some of his "photogenic drawings"—the first "silver prints" ever obtained—were exhibited in this Institution by Michael Faraday. In the same month he communicated his first paper on a photographic process to the Royal Society, and in the following month he read a second paper before the same Society, giving the method of preparing the sensitive paper and of fixing the prints. The outcome of this work was the "Calotype" or Talbotype process, which was sufficiently perfected for portraiture by 1840, and which was fully described in a paper communicated to the Royal Society in 1841. The following year Fox Talbot received the Rumford Medal for his "discoveries and improvements in photography."[1]

Herschel's process consisted in coating a glass plate with silver chloride by subsidence. The details of the method, from Herschel's own notes, have been published by his son, Prof. Alexander Herschel.[2] By this means the old 40-foot reflecting telescope at Slough was photographed in 1839. By the kindness of Prof. Herschel, and with the sanction of the Science and Art Department, Herschel's original photographs have been sent here for your inspection. The process of coating a plate by allowing a precipitate to settle on it in a uniform film is, however, impracticable, and was not further developed by its illustrious discoverer. We must credit him, however, as being the first to use glass as a substratum. Herschel further discovered the important fact that while the chloride was very insensitive alone, its sensitiveness was greatly increased by washing it with a solution of silver nitrate. It is to Herschel, also, that we are indebted for the use of sodium thiosulphate as a fixing agent, as well as for many other discoveries in connection with photography, which are common matters of history.

Admitting the impracticability of the method of subsidence for producing a sensitive film, it is interesting to trace the subsequent development of the processes inaugurated about the year 1839. The first of photographic methods—the bitumen process of Niepce—survives at the present time, and is the basis of some of the most important of modern photo-mechanical printing processes. [Specimens illustrating photo-etching from Messrs. Waterlow and Sons exhibited.] The Daguerreotype process is now obsolete. As it left the hands of its inventor it was unsuited for portraiture, on account of the long exposure required. It is evident, moreover, that a picture on an opaque metallic plate is incapable of reproduction by printing through, so that in this respect the Talbotype possessed distinct advantages. This is one of the most important points in Fox Talbot's contributions to photography. He was the first to produce a transparent paper negative from which any number of positives could be obtained by printing through. The silver print of modern times is the lineal descendant of the Talbotype print. After forty years' use of glass as a substratum, we are going back to Fox Talbot's plan, and using thin flexible

[1] "An Account of a Method of Copying Paintings upon Glass, and of making Profiles by the Agency of Light upon Nitrate of Silver. Invented by T. Wedgwood, Esq. With Observations by H. Davy." Journ. R.I., 1802, p. 170.

[1] For these and other details relating to Fox Talbot's work, necessarily excluded for want of time, I am indebted to his son, Mr. C. H. Talbot, of Lacock Abbey.

films—not exactly of paper, but of an allied substance, celluloid. [Specimens of Talbotypes, lent by Mr. Crookes, exhibited, with celluloid negatives by the Eastman Company.]

If I interpret this fragment of history correctly, the founders of modern photography are the three men whose labours have been briefly sketched. The jubilee of last autumn marked a culminating point in the work of Niepce and Daguerre, and of Fox Talbot. The names of these three pioneers must go down to posterity as co-equal in the annals of scientific discovery. [Portraits by Mr. H. M. Elder shown.] The lecture theatre of the Royal Institution offers such tempting opportunities to the chronicler of the history of this wonderful art that I must close this treatment of the subject by reminding myself that in selecting the present topic I had in view a statement of the case of modern photography from its scientific side only. There is hardly any invention associated with the present century which has rendered more splendid services in every department of science. The physicist and chemist, the astronomer and geographer, the physiologist, pathologist, and anthropologist will all bear witness to the value of photography. The very first scientific application of Wedgwood's process was made here by the illustrious Thomas Young, when he impressed Newton's rings on paper moistened with silver nitrate, as described in his Bakerian Lecture to the Royal Society on November 24, 1803. Prof. Dewar has just placed in my hands the identical slide with the Newton rings still visible, which he believes Young to have used in this classic experiment. [Shown.]

Our modern photographic processes depend upon chemical changes wrought by light on films of certain sensitive compounds. Bitumen under this influence becomes insoluble in hydrocarbon oils, as in the heliographic process of the elder Niepce. Gelatine mixed with potassium dichromate becomes insoluble in water on exposure to light, a property utilized in the photo-etching process introduced in 1852 by Fox Talbot, some of whose original etchings have been placed at my disposal by Mr. Crookes. [Shown.] Chromatized gelatine now plays a most important part in the autotype and many photo-mechanical processes. The salts of iron in the ferric condition undergo reduction to the ferrous state under the influence of light in contact with oxidizable organic compounds. The use of these iron salts is another of Sir John Herschel's contributions to photography (1842), the modern "blue print" and the beautiful platinotype being dependent on the photo-reducibility of these compounds. [Cyanotype print developed with ferricyanide.]

Of all the substances known to chemistry at the present time, the salts of silver are by far the most important in photography on account of the extraordinary degree of sensitiveness to which they can be raised. The photographic image with which it is my privilege to deal on this occasion is that invisible impression produced by the action of light on a film of a silver haloid. Many methods of producing such films have been in practical use since the foundation of the art in 1839. All these depend on the double decomposition between a soluble chloride, bromide, or iodide, and silver nitrate, resulting in the formation of the silver haloid in a vehicle of some kind, such as albumen (Niepce de St. Victor, 1848) or collodion on glass, as made practicable by Scott Archer in 1851. For twenty years this collodion process was in universal use; its history and details of manipulation, its development into a dry plate process by Colonel Russell in 1861, and into an emulsion process by Bolton and Sayce in 1864, are facts familiar to everyone.

The photografphic film of the present time is a gelatino-haloid (generally bromide) emulsion. If a solution of silver nitrate is added to a solution of potassium bromide and the mixture well shaken, the silver bromide coagulates and rapidly subsides to the bottom of the liquid as a dense curdy precipitate. [Shown.] If instead of water we use a viscid medium, such as gelatine solution, the bromide does not settle down, but forms an emulsion, which becomes quite homogeneous on agitation. [Shown.] This operation, omitting all details of ripening, washing, &c., as well known to practical photographers, is the basis of all the recent photographic methods of obtaining negatives in the camera. The use of this invaluable vehicle, gelatine, was practically introduced by R. L. Maddox in 1871, previous experiments in the same direction having been made by Gaudin (1853–61). Such a gelatino-bromide emulsion can be spread uniformly over any substratum—glass, paper, gelatine, or celluloid—and when dry gives a highly sensitive film.

The fundamental problem which fifty years' experience with silver haloid films has left in the hands of chemists is that of the nature of the chemical change which occurs when a ray of light falls on such a silver salt. Long before the days of photography—far back in the sixteenth century—Fabricius, the alchemist, noticed that native horn silver became coloured when brought from the mine and exposed. The fact presented itself to Robert Boyle in the seventeenth century, and to Beccarius, of Turin, in the eighteenth century. The change of colour undergone by the chloride was first shown to be associated with chemical decomposition in 1777 by Scheele, who proved that chlorine was given off when this salt darkened under water. I can show you this in a form which admits of its being seen by all. [Potassium iodide and starch paper were placed in a glass cell with silver chloride, and the arrangement exposed to the electric light till the paper had become blue.] The gas which is given off under these circumstances is either the free halogen or an oxide or acid of the halogen, according to the quantity of moisture present and the intensity of the light. I have found that the bromide affects the iodide and starch paper in the same way, but silver iodide does not give off any gas which colours the test paper. All the silver haloids become coloured on exposure to light, the change being most marked in the chloride, less in the bromide, and least of all in the iodide. The latter must be associated with some halogen absorbent to render the change visible. [Strips of paper coated with the pure haloids, the lower halves brushed over with silver nitrate solution, were exposed.] The different degrees of coloration in the three cases must not be considered as a measure of the relative sensitiveness: it simply means that the products of photo-chemical change in the three haloids are inherently possessed of different depths of colour.

From the fact that halogen in some form is given off, it follows that we are concerned with photo-chemical decomposition, and not with a physical change only. All the evidence is in favour of this view. Halogen absorbents, such as silver nitrate on the lower halves of the papers in the last experiment, organic matter, such as the gelatine in an emulsion, and reducing agents generally, all accelerate the change of colour. Oxidizing and halogenizing agents, such as mecuric chloride, potassium dichromate, &c., all retard the colour change. [Silver chloride paper, painted with stripes of solutions of sodium sulphite, mercuric chloride, and potassium dichromate, was exposed.] It is impossible to account for the action of these chemical agents except on the view of chemical decomposition. The ray of light falling upon a silver haloid must be regarded as doing chemical work; the vibratory energy is partly spent in doing the work of chemical separation, and the light passes through a film of such haloid partly robbed of its power of doing similar work upon a second film. It is difficult to demonstrate this satisfactorily in the lecture-room on account of the opacity of the silver haloids, but the work of Sir John Herschel, J. W. Draper, and others has put it beyond doubt that there is a relationship of this kind between

absorption and decomposition. It is well known also that the more refrangible rays are the most active in promoting the decomposition in the case of the silver haloids. This was first proved for the chloride by Scheele, and is now known to be true for the other haloids. It would be presumption on my part in the presence of Captain Abney to enlarge upon the effects of the different spectral colours on these haloids, as this is a subject upon which he can speak with the authority of an investigator. It only remains to add that the old idea of a special "actinic" force at the more refrangible end of the spectrum has long been abandoned. It is only because the silver haloids absorb these particular rays that the blue end of the spectrum is most active in promoting their decomposition. Many other instances of photo-chemical decomposition are known in which the less refrangible rays are the most active, and it is possible to modify the silver haloids themselves so as to make them sensitive for the red end of the spectrum.

The chemical nature of the coloured products of photo-chemical decomposition is still enshrouded in mystery. Beyond the fact that they contain less halogen than the normal salt, we are not much in advance of the knowledge bequeathed to us by Scheele in the last century. The problem has been attacked by chemists again and again, but its solution presents extraordinary difficulties. These products are never formed—even under the most favourable conditions of division and with prolonged periods of exposure—in quantities beyond what the chemist would call "a mere trace." Their existence appears to be determined by the great excess of unaltered haloid with which they are combined. Were I to give free rein to the imagination, I might set up the hypothesis that the element silver is really a compound body invariably containing a minute percentage of some other element, which resembles the compound which we now call silver in all its chemical reactions, but alone is sensitive to light. I offer this suggestion for the consideration of the speculative chemist.[1] For the coloured product as a whole, *i.e.* the product of photo-decomposition with its combined unchanged haloid, Carey Lea has proposed the convenient term "photosalt." It will avoid circumlocution if we adopt this name. The photosalts have been thought at various times to contain metallic silver, allotropic silver, a sub-haloid, such as argentous chloride, &c., or an oxyhaloid. The free metal theory is disposed of by the fact that silver chloride darkens under nitric acid of sufficient strength to dissolve the metal freely. The acid certainly retards the formation of the photosalt, but does not prevent it altogether. When once formed the photo-chloride is but slowly attacked by boiling dilute nitric acid, and from the dry photosalt mercury extracts no silver. The assumption of the existence of an allotropic form of silver insoluble in nitric acid cannot be seriously maintained. The sub-haloid theory of the product may be true, but it has not yet been established with that precision which the chemist has a right to demand. We must have analyses giving not only the percentage of halogen, but also the percentage of silver, in order that it may be ascertained whether the photosalt contains anything besides metal and halogen. The same may be said of the oxyhaloid theory: it may be true, but it has not been demonstrated.

The oxyhaloid theory was first suggested by Robert Hunt[2] for the chloride; it was taken up by Sahler, and has recently been revived by Dr. W. R. Hodgkinson. It has been thought that this theory is disposed of by the fact that the chloride darkens under liquids, such as hydrocarbons, which are free from oxygen. I have been repeating some of these experiments with various liquids, using every possible precaution to exclude oxygen and moisture; dry silver chloride heated to incipient fusion has been sealed up in tubes in dry benzene, petroleum, and carbon tetrachloride and exposed since March. [Tubes shown.] In all cases the chloride has darkened. The salt darkens, morever, in a Crookesian vacuum.[1] By these experiments the oxychloride theory may be scotched, but it is not yet killed; the question now presents itself, whether the composition of the photosalt may not vary according to the medium in which it is generated. Analogy sanctions the supposition that when the haloid darkens under water or other oxygen-containing liquid, or even in contact with moist or dry air, that an oxychloride may be formed, and enter into the composition of the photosalt. The analogy is supplied by the corresponding salt of copper, viz. cuprous chloride, which darkens rapidly on exposure. [Design printed on flat cell filled with cuprous chloride by exposure to electric light.] Wöhler conjectured that the darkened product was an oxychloride, and this view receives a certain amount of indirect support from these tubes [shown], in which dry cuprous chloride has been sealed up in benzene and carbon tetrachloride since March; and although exposed in a southern window during the whole of that time, the salt is as white as when first prepared. Some cuprous chloride sealed up in water, and exposed for the same time, is now almost black. [Shown.]

When silver is precipitated by reduction in a finely divided state in the presence of the haloid, and the product treated with acids, the excess of silver is removed and coloured products are left which are somewhat analogous to the photosalts proper. These coloured haloids are also termed by Carey Lea photosalts because they present many analogies with the coloured products of photo-chemical change. Whether they are identical in composition it is not yet possible to decide, as we have no complete analyses. The first observations in this direction were published more than thirty years ago in a report by a British Association Committee,[2] in which the red and chocolate-coloured chlorides are distinctly described. Carey Lea has since contributed largely to our knowledge of these coloured haloids, and has at least made it appear highly probable that they are related to the products formed by the action of light. [Red photo-chloride and purple photobromide and iodide shown.]

The photographic image is impressed on a modern film in an inappreciable fraction of a second, whereas the photosalt requires an appreciable time for its production. The image is invisible simply because of the extremely minute quantity of haloid decomposed. In the present state of knowledge it cannot be asserted that the material composing this image is identical in composition with the photosalt, for we know the composition of neither the one nor the other. But they are analogous in so far as they

[1] I have gone so far as to test this idea experimentally in a preliminary way, the result being, as might have been anticipated, negative. Silver chloride, well darkened by long exposure, was extracted with a hot saturated solution of potassium chloride, and the dissolved portion, after precipitation by water, compared with the ordinary chloride by exposure to light. Not the slightest difference was observable either in the rate of coloration or in the colours of the products. Perhaps it may be thought worth while to repeat the experiment, using a method analogous to the "method of fractionation" of Crookes.

[2] "Researches on Light," 2nd ed., 1854, p. 80.

[1] Some dry silver chloride which Mr. Crookes has been good enough to seal up for me in a high vacuum darkens on exposure quite as rapidly as the dry salt in air. It soon regains its original colour when kept in the dark. It behaves, in fact, just as the chloride is known to behave when sealed up in chlorine, although its colour is of course much more intense after exposure than is the case with the chloride in chlorine.

[2] These results were arrived at in three ways. In one case hydrogen was passed through silver citrate suspended in hot water, and the product extracted with citric acid. "The result of treating the residue with chlorhydric acid, and then dissolving the silver by dilute nitric acid, was a rose-tinted chloride of silver." In another experiment the dry citrate was heated in a stream of hydrogen at 212° F., and the product, which was partly soluble in water, gave a brown residue, which furnished "a very pale red body on being transformed by chlorhydric and nitric acids." In another experiment silver arsenite was formed, this being treated with caustic soda, and the black precipitate then treated successively with chlorhydric and nitric acids: "Silver is dissolved, and there is left a substance . . . . [of] a rich chocolate or maroon, &c." This on analysis was found to contain 24 per cent. of chlorine, the normal chloride requiring 24·74 and the sub-chloride 14·08 per cent. The Committee which conducted these experiments consisted of Messrs. Maskelyne, Hadow Hardwick, and Llewelyn. B.A. Rep., 1859, p. 103.

are both the result of photo-chemical decomposition, and there is great probability that they are closely related, if not identical, chemically. It may turn out that there are various kinds of invisible images, according to the vehicle or halogen absorbent—in other words, according to the sensitizer with which the silver haloid is associated. The invisible image is revealed by the action of the developer, into the function of which I do not propose to enter. It will suffice to say that the final result of the developing solution is to magnify the deposit of photosalt by accumulating metallic silver thereon by accretion or reduction. Owing to the circumstance that the image is impressed with such remarkable rapidity, and that it is invisible when formed, it has been maintained, and is still held by many, that the first action of light on the film is molecular or physical, and not chemical. The arguments in favour of the chemical theory appear to me to be tolerably conclusive, and I will venture to submit a few of them.

The action of reagents upon the photographic film is quite similar to the action of the same reagents upon the silver haloids when exposed to the point of visible coloration. Reducing agents and halogen absorbents increase the sensitiveness of the film: oxidizing and halogenizing agents destroy its sensitiveness. It is difficult to see on the physical theory why it should not be possible to impress an image on a film, say of pure silver bromide, as readily as on a film of the same haloid embedded in gelatine. Everyone knows that this cannot be done. I have myself been surprised at the extreme insensitiveness of films of pure bromide prepared by exposing films of silver deposited on glass to the action of bromine vapour. On the chemical theory we know that gelatine is a splendid sensitizer—*i.e.* bromine absorbent. There is another proof which has been in our hands for nearly thirty years, but I do not think it has been viewed in this light before. It has been shown by Carey Lea, Eder, and especially by Abney—who has investigated the matter most thoroughly—that a shearing stress applied mechanically to a sensitive film leaves an impression which can be developed in just the same way as though it had been produced by the action of light. [Pressure marks on Eastman bromide paper developed by ferrous oxalate.] Now that result cannot be produced on a surface of the pure haloid: some halogen absorbent, such as gelatine, must be associated with the haloid. We are concerned here with a chemical change of that class so ably investigated by Prof. Spring, of Liége, who has shown that by mere mechanical pressure it is possible to bring about chemical reaction between mixtures of finely divided solids.[1] Then again, mild reducing agents, too feeble to reduce the silver haloids directly to the metallic state, such as alkaline hypophosphites, glucose or lactose and alkali, &c., form invisible images which can be developed in precisely the same way as the photographic image. All this looks like chemical change, and not physical modification pure and simple.

I have in this discourse stoically resisted the tempting opportunities for pictorial display which the subject affords. My aim has been to summarize the position in which we find ourselves with respect to the invisible image after fifty years' practice of the art. This image is, I venture to think, the property of the chemist, and by him must the scientific foundation of photography be laid. We may not be able to give the formula of the photosalt, but if the solution of the problem has hitherto eluded our grasp it is because of the intrinsic difficulties of the investigation. The photographic image brings us face to face—not with an ordinary, but with an extraordinary class of chemical changes due entirely to the peculiar character of the silver salts. The material composing the image is not of that definite nature with which modern chemical methods are in the habit of dealing. The stability of the photosalt is determined by some kind of combination between the sub-haloid or oxyhaloid, or whatever it may be, and the excess of unaltered haloid which enters into its composition. The formation of the coloured product presents certain analogies with the formation of a saturated solution; the product of photo-chemical decomposition is formed under the influence of light up to a certain percentage of the whole photosalt, beyond which it cannot be increased—in other words, the silver haloid is saturated by a very minute percentage of its own product of photo-decomposition. The photosalt belongs to a domain of chemistry—a no-man's land—peopled by so-called "molecular compounds," into which the pure chemist ventures but timidly. But these compounds are more and more urging their claims for consideration, and sooner or later they will have to be reckoned with, even if they lack that definiteness which the modern chemist regards as the essential criterion of chemical individuality. The investigation may lead to the recognition of a new order of chemical attraction, or of the old chemical attraction in a different degree. The chemist who discourses here upon this subject at the end of the half-century of photography into which we have now entered will no doubt know more about this aspect of chemical affinity; and if I may invoke the spirit of prophecy in concluding, I should say that a study of the photographic film with its invisible image will have contributed materially to its advancement.

1 The connection between the two phenomena was suggested during a course of lectures delivered by me two years ago ("Chemistry of Photography," p. 191). I have since learnt that the same conclusion had been arrived at independently by Mr. C. H. Bottomley, of the Yorkshire College, Leeds.

THE VELOCITIES OF PROJECTILES.[1]

THE experimenters, whose work is recorded in the papers noted below, have succeeded admirably in their attempts to photograph projectiles while moving with their ordinary velocities. At the same time, they have obtained indications of the forms of the waves excited in the air by projectiles when moving with velocities higher than the normal velocity of sound in the air.

The first experiments were conducted by Mach and Wentzel with velocities of the projectiles about 240 m.s. (787 f.s.), which were below the normal velocity of sound, when they obtained only negative results. After this, Mach and Salcher carried on experiments of the same nature with three small arms, which respectively gave muzzle velocities of 438 m.s. (1437 f.s.), 338 m.s. (1100 f.s.), and 522 m.s. (1713 f.s.). The arrangements were such that, when the projectile was in the focus of the camera lens, it caused the discharge of a spark from a Leyden jar at a point in the axis of the lens which was more distant from the lens than the projectile. As the illumination was necessarily of very short duration, the instantaneous photographs were taken on a small scale. These photographs showed a well-defined wave of condensation of the air in front of the projectile when the velocity of the shot exceeded that of sound, or about 340 m.s. (1116 f.s.). All the experiments of value were

made by the two small arms, which gave muzzle velocities of 1437 f.s. and 1713 f.s. When proper arrangements were made, the photographs of the projectiles fired by these two guns were always very fine and sharp. With a sufficient velocity of the shot, the limit of the condensed air-wave in front of the projectile appeared to be of a hyperboloidal form, whose vertex was in advance of the projectile, and axis in the line of flight. Similar traces in the photograph, indicating conical waves whose axes were also in the line of flight, took their rise from the base of the shot. Other but weaker traces of waves of air took their rise from points on the surface of the shot. All these straight lines in the photograph were inclined to the line of flight at a rather less angle than the traces of the head wave. When the velocity of the projectile was increased, the angles which the traces of the waves made with the line of flight were diminished.

When the highest velocities were obtained, the channel vacated by the projectile was immediately filled with peculiar little clouds, which appeared almost as regular and symmetrical as beads strung on a line stretched in the direction of the line of flight. And there was no indication of a vacuum in the rear of the shot, even when the velocity was so high as 900 m.s. (2953 f.s.). As the air was transparent, the form of the waves of air in the photographs must have been caused by the varying density of the air, which refracted the rays of light.

Long ago Robins noticed a change in the law of resistance of the air to projectiles at about the velocity of sound. Although Hutton disputed this change in the law of resistance and others ignored it, recent experiments have completely confirmed Robins's discovery. It now appears that the disturbances caused by the projectile in the air travel faster than the shot for low velocities, so that the compression of the air in front of the projectile is not sufficient to cause traces of waves in the photographs.

The two guns which gave satisfactory results with muzzle velocities of 1437 f.s. and 1713 f.s., showed widely different curvatures at the vertex of the wave of condensation in advance of the projectile. It was therefore very desirable that the velocity of the shot should have been exactly determined at the moment each photograph was taken. This condition has unfortunately not been sufficiently attended to, for although an improvised ballistic pendulum was used in some cases, it was soon discarded.

Afterwards the experimenters made use of guns of larger calibre. Salcher carried out experiments at Pola with a gun of 9 cm. (3·5 inches) calibre, which gave a muzzle velocity of 448 m.s. (1470 f.s.). Other experiments were made at Meppen, by Mach, assisted by his son, with a gun of 4 cm. (1·6 inch) calibre, which gave a muzzle velocity of 670 m.s. (2198 f.s.). The head wave appeared as a stronger and broader hyperbolic curve in the photograph, which was rather more in advance of the head of the shot than in the case where small arms were used. But when the velocities of the shot were nearly the same in the two cases, the traces of the waves in the photographs made nearly the same angle with the line of flight. This perhaps might have been expected, as it has been found experimentally that the resistance of the air to projectiles varies as the square of their diameter.

Further experiments were afterwards carried out in the laboratory. In this case projectiles composed of various metals were used, as brass, aluminium, and lead, which were of various forms. Attempts were made to determine the velocities of the projectiles in two different ways, neither of which can be regarded as quite satisfactory. In one case it was assumed that the work done on the projectile by a given charge of powder would be constant. But this assumption would not be true for considerable variations in the weight of the projectile. In the other case, the velocity was calculated by using the inclination, a, of the trace of the rear wave in the photograph to the line of flight, on the supposition that the velocity of sound = velocity of the projectile $\times$ sin a.

Much labour and ingenuity have been expended in bringing these experiments to their present satisfactory state. The ground has been well prepared for sets of systematic experiments made with useful forms of projectiles fired with various muzzle velocities. The results given by spherical projectiles might prove useful to the theorist. Other experiments might be carried out with ogival, hemispherical, and flat-headed elongated projectiles. In all cases the readings of the barometer and thermometer should be recorded, and the velocity of the projectile should be measured. The ballistic pendulum would probably give the best results if the block was shielded from the action of the wave of condensed air which accompanies the projectile.

Further, E. Mach has attempted to compare the velocity of the report of a gun with that of the projectile. In one series of his experiments, when the terminal velocity of the projectile was higher than the normal velocity of sound, the time of flight of the projectile, and the time in which the report of the gun travelled over the same distance, agreed very closely. But in another series, where the terminal velocity of the projectile was below that of sound, it was found that the time of flight of the projectile was greater than that of the report of the gun over the same distance. It was therefore considered that the report of the gun travels at the same velocity as the projectile so long as the velocity of the projectile is greater than that of sound. But when the velocity of the projectile is reduced by the resistance of the air below the velocity of sound, then the report of the gun travels in advance of the projectile, moving with the normal velocity of sound. As experiments are frequently made with velocities of the projectile more than double that of sound, there seems to be no difficulty in the way of deciding whether the report of a gun travels at the same velocity as the projectile for high velocities. If so, as appears probable, there arises the question as to the velocity with which the report of the gun travels in various directions from the muzzle of the gun. If a stretched membrane could be made to interrupt a galvanic current for a moment on the passage of a sound-wave, it would not be difficult to determine the law of propagation of the report of a gun in all horizontal directions. For the projectile might be made to cut equidistant screens, and if lines of properly prepared membranes, at the same distance apart as the screens, were run in various directions, each line being provided with its own galvanic current and marker, the progress of the projectile and of the report of the gun in the chosen directions might be registered on the surface of a cylinder rotating with a known velocity. B.

NOTES.

ON Friday last, Mr. Isaac Roberts, F.R.S., of Maghull, Liverpool, was presented with an address on the occasion of his removal from Liverpool to his new observatory near Tunbridge Wells. The presentation took place in the Council Chamber at the Town Hall before a large and representative assembly. The Mayor (Mr. Thomas Hughes), who presided, referred in eulogistic terms to the services rendered to astronomy by Mr. Roberts in his chosen field of celestial photography. Principal Rendall proposed the adoption of the address, in which reference was made to Mr. Roberts's long and honourable business career in Liverpool, and to the important discoveries made by him in stellar photography. The address was signed by the Mayor, Principal Rendall and the Professorial staff of University College, many members of the City Council and of learned and scientific Societies in Liverpool, and other prominent citizens. Mr. John Hartnup, of the Bidston Observatory, seconded the motion, and

it was supported by Mr. A. G. White, the President of the Master Builders' Association. The Mayor then made the presentation. Mr. Roberts, in responding, drew attention to the fact that the city contained no monument or record of the labours of the two great Liverpool astronomers, Lassell and Jeremiah Horrocks, and expressed his willingness to join in any movement having that object in view. He also explained that his reasons for leaving Liverpool were because of the unsuitable nature of the atmosphere for taking observations.

IT is expected that the Electrical Standards Committee will arrange for a discussion, at the Leeds meeting of the British Association, on the best values to adopt for the units of electrical measurement.

MR. W. C. MACDONALD, a merchant of Montreal, has just made a munificent contribution to McGill College. He has given 150,000 dollars to the Law Faculty for the endowment of the Dean's and another chair, and also 50,000 dollars for the endowment of a Chair of Experimental Physics, and has offered to erect buildings for the Faculty of Applied Science, to include class-rooms and laboratories. Altogether, the value of Mr. Macdonald's gift is about 400,000 dollars.

AT a meeting of the Council of the South Wales University College on the 2nd inst., Mr. Archibald C. Elliott was elected to the Engineering Professorship just founded at Cardiff.

THE death took place, on the 29th ult., of Mr. Alexander Parkes, of West Dulwich, and formerly of Birmingham, at the age of seventy-six years. Mr. Parkes was well known as the inventor of the substance parkesine or celluloid, and also of many important manufacturing and metallurgical processes.

THE death, on the 2nd inst., is announced of Mr. John Page, chief engineer of the canals of the Canadian Dominion, and the projector and constructor of the enlarged St. Lawrence Canal system.

THE German Emin Pasha Relief Committee has received a telegram announcing the arrival of Dr. Peters with his Expedition in Usugara.

AT the invitation of Sir William MacGregor, Mr. C. Hedley, of the scientific staff of the Queensland Museum, has gone to New Guinea for the purpose of making a thorough scientific investigation of the invertebrate fauna of the east coast of that country.

MR. JAMES BENNETT has (according to the *Colonies and India*) been commissioned by Lord Knutsford to proceed to Lagos, to make full inquiry into and report upon the mineral and vegetable resources of the colony with a view to their further development. Mr. Bennett is the inventor of a special process for extracting, by means of chemicals, pure rubber from the milk of the wild fig-tree, of which several species are to be found in Lagos and the neighbourhood, and it seems likely that considerable advantage will accrue to the colony from his visit. Mr. Bennett will devote particular attention to such products as rubber, gums, fibres, and minerals, in which it is thought that the present trade of the colony may be largely increased, or which are considered likely to become subjects of local manufacture.

MR. BROWN, the South Australian Government Geologist, has left Adelaide for the north, having been specially commissioned to carry out the geological survey of the Macdonnell Ranges, and to report on the Hale River gold-field. He will be joined on the journey by two members of the Board already selected, and some valuable work will, it is thought, be accomplished by the party before they return.

ACCORDING to the Report of the Oxford University Extension scheme which has been issued, and which comes up to the commencement of July, "Since June 1889, 148 courses have been delivered in 109 centres by 25 lecturers. Examinations were held at the conclusion of 119 courses, and the examiners have awarded certificates of merit or distinction to 927 candidates. The courses were attended by 17,854 students, and the average period of study covered by each course was 10 weeks." In 1885-86 the number of courses delivered was 27 only, and the number of lecture centres 22. Amongst the chief signs of progress recorded are (1) a great extension of University teaching in small towns; (2) a marked increase in the number of working men attending the lectures; (3) the arrangement of a number of successful and well-attended courses during the early summer months; (4) the establishment of 36 Students' Associations at various centres; and (5) the federation in two new districts of the various lecture centres. The Students' Associations are very valuable, inasmuch as "they encourage the students to undertake regular reading throughout the year in preparation for, or in continuation of, the courses of lectures." The federation movement is also extremely helpful. It enables the difficulty sometimes experienced in procuring lecturers to be more easily surmounted, and it fosters and stimulates local interest in the study undertaken. The Committee regrets that a greater proportion of students do not present themselves for examination, but those who do go through the ordeal appear, on the whole, to come out very creditably. Scholarships are given to the writers of the best essays on a number of subjects connected with those studied during the course; and "amongst the successful essayists," we are told, "were two carpenters, two clerks, a fustian weaver, an artisan employed in a Government dockyard, and three elementary teachers." In an examination recently held, those who were awarded certificates included "a national schoolmistress, a young lawyer, a plumber, and a railway signalman." Again, we are informed that "a course of lectures on zoology recently given by an Oxford lecturer in Devonshire was attended by a student whose essays convinced the lecturer of her singular powers of accurate and original observation. She was encouraged by the lecturer to undertake a course of systematic study, and at his suggestion became a candidate in the examination for scholarships at Somerville Hall, where she was elected to the second scholarship."

AT the third summer meeting of University Extension and other students, which is to be held at Oxford in August, Mr. E. B. Poulton, F.R.S., will lecture on the influence of courtship on colour, and Mr. Francis Gotch on the physiology of the nervous system; Prof. Patrick Geddes will deal with problems of evolution, organic and social; Prof. Green, F.R.S., will give a course on geology; and Mr. C. Carus-Wilson lectures on geological phenomena. The teaching of geography, by Mr. H. J. Mackinder; protective adaptations in plants, by Mr. J. B. Farmer; and some aspects of light, by Mr. V. Perronet Sells, are also subjects announced in the programme.

DURING the cruise of the *Garland* on the west coast of Scotland in June, for the purpose of examining oyster and mussel grounds, Mr. Anderson Smith records the following captures of more especial interest to naturalists. The large *Pennatula quadrangularis* was found to be commonly distributed in great abundance in several lochs. The rare *Isocardia cor* was taken in the trawl in Loch Sunart, alive. *Balanoglossus* was obtained from deep water off Dunvegan, Skye, and may be considered the first specimen recorded from Scotland. The rare fish *Cepola rubescens*, L., or Red Band-fish, was taken off Jura, and is an addition to the fauna of the outer waters, although one or more specimens have been recorded from the Clyde area. Among *Crustacea* many interesting species were found, and the individual supply was such as to lead to the presence at some time or other of a more plentiful fish supply than was met with during the cruise.

A TELEGRAM from Quilimane announces the departure of an Expedition to Zumbo, under the command of Captain Soares d'Andrea, overseer of the River Zambesi. Satisfactory news is said to have been received of Senhor Joaquin Almeida's Expedition to Gungunghama, which landed at Chaichai, 30 miles above the mouth of the River Limpopo, on its way to Gazaland. Good news has also been received from Captain Cerales, in Bilene.

THE latest information of the Russian Expedition to Tibet, under the command of Colonel Pevtsoff, is contained in the following letter from the mining engineer Bogdanovitch, published by the Russian newspaper the *Messenger of the Volga*:—"Having happily passed through the winter at Nia, the Expedition set out on April 24 to traverse the defile of Idjelik-Khanoum, and thus reach Tibet. Colonel Pevtsoff had sent half his camels, carrying 23 bales with his collections, to the banks of the Cherchen River, where they could recover their strength with the abundant pasture. These animals are intended to facilitate our return to Russia. Our baggage will be carried into Tibet on oxen hired for the purpose. We ourselves are riding thither on horseback, carrying with us the light portion of our effects. We left Nia with 30 horses. During the winter M. Roborovsky made an excursion to Cherchen, and I made one to the mountains of Karangon-Fag, south of Khoten. During my tour I met Grombchevsky, who came with me to Khoten in February, and thence returned for a short time to Nia. The health of all the members of the Expedition is perfect, and during the winter we have received all our letters and papers from St. Petersburg, thanks to the good offices of M. Petrovsky, our Consul at Kashgar. We shall send our collections to Russia through his agency." M. Grombchevsky has informed the military Governor of the Syr-Darya district that the time of his journey has been extended until January 15, 1891. His Expedition has already traversed 5000 versts. M. Grombchevsky will pass the summer in exploring Tibet between Polon-Lhasa and Rudok.

THE July number of the *Kew Bulletin* contains further information on the cultivation and preparation of the colouring substance known as annatto. The present instalment deals with the West African seed, which does not appear to possess the qualities of that from Jamaica. A new method of preserving grain from weevils is suggested, while there is a long correspondence on Colombian india-rubber. The letters contain an account of a tree which yields rubber, and which is known in commerce as "Colombia Virgen." It has the peculiarity of growing at high elevations, and therefore in a comparatively cool climate. Another section deals with the fibre industry of the Bahamas, and particulars are given of the establishment of the botanical station at Lagos, the first of its kind on the West Coast of Africa. A letter from the Curator, Mr. McNair, gives interesting information respecting some of the plants under experimental cultivation there.

AN appendix to the *Bulletin* contains a list of new garden plants, including not only those brought into cultivation for the first time during 1889, but the most noteworthy of those which had been re-introduced after being lost from cultivation. Other plants included in the lists have been in gardens for several years, but either were not described or their names had not been authenticated until recently. All hybrids, whether introduced or of garden origin, described for the first time in 1889, are included. The list contains a reference to the place where the plant is first described or figured, or where additional information is given; besides the natural order and country, a brief notice of the habit and most striking points of each plant is given.

THE Lucayan Indians, who inhabited the islands now called the Bahamas, were the first Indians seen by Columbus. In less than twenty years this interesting people, numbering, according to the estimate of the conquerors, 40,000 persons, was wholly exterminated. The hammock was found among the Lucayans, and both the word and the thing were adopted by the Spaniards, through whom they were passed on to other nations. Various skulls have been recovered from caves in the Bahamas, and have been made the subject of a valuable paper by Mr. W. K. Brooks. This paper was read some time ago before the National Academy of Sciences, America, and has now been reprinted as a separate memoir, with carefully executed illustrations. Columbus testifies that the Lucayans were "of good size, with large eyes and broader foreheads than he had ever seen in any other race of men"; and Mr. Brooks says this agrees perfectly with the results he has reached, the most conspicuous characteristics of the skulls he has examined being the great breadth noted by Columbus, and the massiveness and solidity of the head. "We may, therefore, unhesitatingly decide," says Mr. Brooks, "that they are the remains of the people who inhabited the islands at the time of their discovery, and that these people were a well-marked type of that North American Indian race which was at that time distributed over the Bahama Islands, Hayti, and the greater part of Cuba. As these islands are only a few miles from the peninsula of Florida, this race must at some time have inhabited at least the south-eastern extremity of the continent, and it is therefore extremely interesting to note that the North American crania which exhibit the closest resemblance to those from the Bahama Islands have been obtained from Florida."

THE *Times* gives some details of the new expedition to the North Pole, for which the Norwegian National Assembly voted 200,000 kroner on the 30th ult., and which will be under the charge of M. Nansen. Hitherto, with one possible exception, all attempts to reach the North Pole have been made in defiance of the obstacles of Nature. It has been an open campaign between the endurance of man and the icy barrier of the Arctis Seas, in which Nature has always been triumphant. On this occasion a systematic and well-organized attempt will be made to ascertain if Nature herself has not supplied a means of solving the difficulty, and if there is not, after all, a possibility of reaching the North Pole by utilizing certain natural facilities in these frozen seas of which all earlier explorers were ignorant. The circumstances on which these new hopes are founded may be thus summarized. The *Jeannette* Expedition of 1879–81 and the loss of that vessel seemed to sound the knell of all expeditions to reach the Pole by Behring Straits; but in the end the results of that effort are shown to have been more satisfactory and auspicious than any of the officers of the *Jeannette* could have hoped for when, with extreme difficulty, they succeeded in reaching Siberia across the ice from their wrecked vessel. In June 1884, exactly three years after the *Jeannette* sank, there were found near Julianshaab, in Greenland, several articles which had belonged to the *Jeannette* and been abandoned at the time of its wreck by the crew, and which had been carried to the coast of Greenland, from the opposite side of the Polar Sea, on a piece of ice. This fact at once aroused curiosity as to how it accomplished the journey across the Arctic Ocean, and as to what unknown current had borne the message from Behring Straits to Greenland. However these objects reached Julianshaab, they could not have come in an eastern direction, through Smith's Sound, for the only current which reaches Julianshaab is that from the eastern coast of Greenland *viâ* Cape Farewell and the north. Nor is there much probability that they were borne in a western direction from the place where the *Jeannette* sank, for all the currents round Nova Zembla, Franz-Josef Land, and Spitzbergen are known, and it seems impossible for

the ice bearing the relics of the unfortunate *Jeannette* to have traversed the intervening distance in the space of three years, even if it were possible at all. There remains only the alternative that there is a comparatively short and direct route across the Arctic Ocean by way of the North Pole, and that Nature herself has supplied a means of communication, however uncertain, across it. Increased significance to the discovery of the *Jeannette* relics in 1884 was given by the identification in 1886 of bows found on the coast of Greenland with those by the Eskimo in the vicinity of Behring Straits, at Port Clarence, Norton Sound, and the mouth of the Yukon River. M. Nansen's Expedition will endeavour to realize these hopes of a direct route across the apex of the Arctic Ocean. A specially constructed boat of 170 tons will be built, and provisions and fuel taken for five years, although it is hoped that two will suffice. The Expedition will consist of 10 or 12 men, and M. Nansen proposes to leave Norway in February 1892.

THE *Meteorologische Zeitschrift* for June contains summaries, by Dr. T. Hann, of the results of the meteorological observations at the following international Polar stations:—(1) Sodankylä, in Lapland, where observations were made for two years ending August 1884. (2) Möller Bay, in Novaia Zemlia—September 1882 to August 1883. (3) Sagastyr, at the mouth of the Lena —September 1882 to June 1884. The observer at this station remarks that they were all more susceptible of cold in summer than in winter; in autumn this susceptibility ceased. In winter they could expose themselves experimentally for a few minutes to a temperature of about − 58° F., with scarcely any clothing, without any unpleasant feeling. The explanation is probably to be found in the complete stillness of the air at the time.

THE Harvard College has published, as vol. xxii. of its Annals, the very complete and valuable series of meteorological observations made at the summit of Pike's Peak, Colorado, between January 1874 and June 1888. This station is the highest in the world, being 14,134 feet above the sea-level. The observations, which have been prepared for publication under the superintendence of the Chief Signal Officer, contain the actual readings taken several times daily, and for a portion of the time even hourly readings, in addition to monthly means for various hours. General Greely draws attention to several interesting facts resulting from a cursory examination of the data. The maxima of both pressure and temperature occur in July, and the minima in January; the annual march of both elements is the same, and the two curves are almost coincident. The mean temperature for the above period was 19°·3; the maximum observed was 64°, and the minimum −39°. The maximum daily range occurs in July and September (about 14°·3), and the minimum in December (11°·6) which is only about half of the range on the low plateau country to the eastward. The precipitation exhibits peculiarities in its distribution throughout the year; 35 per cent. of the whole amount falls in the summer, and 33 per cent. in spring, the maximum occurring in July and the minimum in February. The mean wind velocity decreases gradually from 26·6 miles per hour in January to 12·5 in July, and 12·3 in August, and it decreases from 2h.–4h. a.m. to 11h. a.m. and noon. The mean hourly velocity during any day rarely exceeds 50 miles; the highest velocity was 112 miles per hour on May 11, 1881, which General Greely states has been frequently exceeded at exposed points on the Atlantic and Pacific coasts. The prevalent direction is from south-west to north-west. Pike's Peak is frequently visited by electrical storms, but they only occur when the air is moist; many interesting details of these are given in the extracts from the observers' journals, at the end of the volume.

THE Chief Signal Officer of the U.S. Army has published a valuable "Supplement to the Monthly Weather Review" for the year 1889, which contains a general discussion of the weather of that year over the United States and Canada, by Captain Dunwoody, illustrated by seven charts prepared from data from about 1000 stations. The annual mean temperature was highest in the southern parts of California, Arizona, and Florida, where it rose above 75°, and it was lowest in Manitoba, where it fell below 35°. The highest maximum temperature was 117° at Yuma, Arizona, on July 3. The highest temperature ever recorded by the Signal Service observers was 119°, at Fort McDowell, Ariz., in 1887. The lowest temperature reported by a regular station of the Signal Service was − 43°, at St. Vincent, Minn., on February 23. The lowest minimum ever reported by a regular station of the Signal Service was − 63°, at Poplar River, Mont., in 1885. With regard to atmospheric pressure, Captain Dunwoody remarks that the effect of marked departures from the usual distribution of monthly mean pressure was noticeable on the paths of the storms. In August and December, for instance, when the pressure over the Southern States was more than 0·1 inch above the normal, no cyclone traversed the country east of the Mississippi and south of the Ohio Rivers. With regard to rainfall, at several of the stations in the Middle Atlantic States, the annual amount was the heaviest ever reported, and the greatest deficiencies occurred in Louisiana and Washington. Fogs occurred in the vicinity of the Banks of Newfoundland most frequently from April to October; in August, fog occurred on 22 days, and in January and December on only 5 and 4 days respectively. The charts show, in addition to the mean values for 1889, the departures of that year from the normal values.

THE occurrence of St. Elmo's fire at sea has been lately studied by Captain Haltermann, of Hamburg, who made examination of a number of ships' log-books for 1884 and 1885, reporting 156 cases, in 800 months of observation (*Met. Zeits.*). He finds a greater number of cases in north than in south latitudes. And of 63 cases observed in the North Atlantic (the stormiest sea in winter) 49 occurred in the months November to April, and only 14 in the other half of the year. Of the total (156) only 27 were unaccompanied by thunder and lightning, and only 6 by precipitates of some kind. Snow and hail showers, with strong wind, seemed specially favourable. Of 133 cases accompanied by rain, there were only 15 without also thunder and lightning; while of 32 with hail, 18 were without thunder and lightning; and of 14 with snow, 12 without thunder and lightning. As to wind, there were instances with all degrees of intensity. The wind was in most cases (beyond 35° lat.) from equatorial direction, and this, with the commonly observed decrease of pressure, indicates that the cases mostly occurred in the front part of depressions. In 46 cases the barometer rose, and in 8 it was unaffected. In most cases the thermometer fell. Between the equator and 10° N. lat. 12 cases were observed, and not one in the corresponding region to the south, where the trade wind generally prevails. In the region of the constantly blowing trade wind St. Elmo's fire is never met with. The western half of seas extending polewards from 30° lat. seems to afford the best conditions. On the whole, the occurrence of St. Elmo's fire may probably be ascribed to the same causes as give rise to thunder and lightning.

MR. J. LLOYD BOZWARD, of Worcester, writes to us that "during a rainstorm on Tuesday (July 1), black rain fell in a district lying between the parishes of Crewle and Broughton Hackett in this county. In road-ruts where rain-water had collected, a considerable film of black sediment remained the day after the storm. The day had been remarkable for a dense canopy of shifting masses of dark-coloured clouds of the nimbus formation. Great rainstorms had been prevalent in this and the adjoining counties. The temperature had been low, and the weather rather like that of November than of July."

MR. L. W. WIGLESWORTH, writing from Brunswick, says:—"I am indebted to a friend for the following observation. A squirrel, in leaping from a height of 33 feet to the ground, caused itself, by means of curving its tail strongly to one side just before alighting, to swerve in its course and so avoid some hard substance upon which it would otherwise have fallen. It landed safely upon a more suitable spot. If no one has done so already, I should like to call attention to the use of the squirrel's tail as a steering and balancing organ during the animal's passages through the air. For other uses see NATURE, vol. xx. p. 603."

THE fresh instalment of the Panama Canal Report deals with the various plans and specifications submitted to the Committee, which are divided into four categories: (1) a canal completely isolated, and making no use of the existing rivers and streams; (2) a canal making use of the existing waterways; (3) a canal with a ship railway over part of the course; (4) a canal with a tunnel through the high land of Culebra. The Report points out the various defects or omissions in the different schemes.

MESSRS. GEORGE BELL AND SONS will publish in a few days an octavo volume entitled "The Diseases of Crops and their Remedies," by Dr. A. B. Griffiths. The work is illustrated with 51 figures, and the chemical treatment of plant diseases is fully discussed.

MR. G. CLARIDGE DRUCE, 118 High Street, Oxford, is compiling a Flora of Berkshire, which will give all available information upon the plants of that county and their distribution through it and the adjoining counties. In order to make the work as complete as possible, the compiler would greatly value any notes on plant occurrences which may be sent to him.

THE schoolmaster, it would seem, is not abroad in Spain, at least as far as geography is concerned. A leading journal of Barcelona announces that England has ceded to Germany Heligoland which is situated on the African coast. This fact suggests to it a number of ingenious political considerations. At the end of the article it is mentioned that Heligoland does not belong to anybody, and is situated between the African territories of Nyanza, Victoria, and the Congo.

SOME very remarkable observations on the production of the ripe figs of *Ficus Roxburghii*, Wall., have recently been published by Dr. D. D. Cunningham, F.R.S., of the Indian Medical Service. The species is diœcious, the male receptacles or figs containing perfect male flowers with pollen, together with imperfect or atrophied female or "gall-flowers," which never produce seed; the female figs contain perfect female flowers only. Both kinds of fig are visited by the "fig-insect," usually a species of *Eupristis*, for the purpose of laying its eggs in the ovary. This is effected in the "gall-flowers" of the male figs; but in the female figs the efforts of the insect to deposit its eggs within the ovary are frustrated by the great thickness of the wall of the ovary. It is very rare to find more than a very few grains of pollen in the female figs; and, according to Dr. Cunningham, the embryo-sac in the female flowers retains, up to the period of the visits of the insect, the character of a uninucleate cell without oosphere, synergidæ, or antipodal vesicles. The full development of the embryo in the female flowers is brought about simply by hypertrophy of the tissues, the result of the stimulation caused by the unsuccessful attempts of the insect to pierce the wall of the ovary. If these observations are confirmed, we have here one of the most remarkable instances of parthenogenesis yet recorded in the vegetable kingdom.

A NEW crystalline carbohydrate, of the composition $C_{18}H_{32}O_{16}$, named by its discoverers *stachyose*, has been extracted by Drs. von Planta and Schulze from the bulbs of *Stachys tuberifera* (*Berichte*, 1890, No. 10, p. 1692). It crystallizes from 90 per cent. alcohol in well-defined hard brilliant crystals belonging to the triclinic system, and containing three molecules of water of crystallization, $C_{18}H_{32}O_{16} + 3H_2O$. When these crystals are powdered, and heated to 103°–104°, they lose their water, leaving a colourless powder consisting of the free carbohydrate $C_{18}H_{32}O_{16}$. The crystals and their aqueous solution possess a faint sweet sugar-like taste, and the solution in water, which is of neutral reaction, rotates the plane of polarization strongly to the right. The solution does not reduce Fehling's solution until after warming with a mineral acid, when reduction rapidly ensues. On heating with nitric acid, the carbohydrate furnishes 37·3 per cent. of mucic acid. When heated with resorcinol and concentrated hydrochloric acid, a deep red coloration is produced. One of the principal products of the inversion of stachyose is galactose, as shown by the following experiment. About 30 grams of stachyose were boiled with a litre of 2½ per cent. sulphuric acid for an hour in a flask furnished with a reflux condenser. After cooling, the sulphuric acid was precipitated by barium hydrate, the barium sulphate filtered off, and the filtrate evaporated to a syrup. On extracting the syrup with 95 per cent. alcohol, and allowing the extract to evaporate over oil of vitriol, crystals slowly separated, possessing, after recrystallization, the right-handed rotation of galactose ($\alpha_D = 80°·5$). From these properties stachyose is considered to belong to the group of carbohydrates termed by Prof. Tollens crystallizable polysaccharides. In this group are included raffinose or mellitose, gentianose, and lactosine. Stachyose resembles the latter substance very closely, especially as regards the formation of galactose on inversion; but it is distinguished from lactosine by its much lower dextro-rotatory power. As regards the preparation of stachyose from the *Stachys tuberifera*, the bulbs were first crushed and the juice extracted as completely as possible by water. The extract was then successively treated with lead acetate and nitrate of mercury, the lead and mercury removed by a current of sulphuretted hydrogen gas, the filtered liquid neutralized with ammonia and evaporated to a thin syrup upon a water-bath. This syrup was then poured into alcohol, when a thick precipitate was formed, which gradually collected as a dark-coloured syrup in the lower portion of the flask. After removal of the alcohol the syrup was dissolved in water, treated with phospho-tungstic acid, and filtered, excess of phospho-tungstic acid being subsequently removed by baryta-water. A stream of carbon dioxide was then led through the liquid, which was again filtered, evaporated, and poured into absolute alcohol, when a perfectly white precipitate was obtained, consisting of almost pure stachyose. The crystals are best obtained by pouring a concentrated aqueous solution of the precipitated carbohydrate into such a quantity of absolute alcohol that a 91 per cent. solution of alcohol is obtained. Crystals of stachyose immediately commence to separate.

FOR the first time since the establishment of the Gardens of the Zoological Society there is now to be seen there one of the ancient breed of the English wild cattle, Earl Ferrers having presented to the Society a fine young bull, which he captured in Chartley Park, Staffordshire. From Garner's "Natural History of Staffordshire" it appears that the wild ox formerly roamed over Needwood Forest. In the thirteenth century William de Farrarus caused the park of Chartley to be separated from the forest, and the turf of this extensive enclosure still remains almost in its primitive state. Here a herd of wild cattle has been preserved down to the present day, and they retain their wild characteristics, like those at Chillingham.

THE additions to the Zoological Society's Gardens during the past week include a Water-buck (*Cobus ellipsiprymnus* ♂), a Serval (*Felis serval*), six Vulturine Guinea Fowls (*Numida*

vulturina), three Mitred Guinea Fowls (*Numida mitrata*) from East Africa, presented by Mr. George S. Mackenzie; a Tawny Owl (*Syrnium aluco*), British, presented by Mr. G. Gurney; a Long-eared Owl (*Asio otus*), British, presented by Miss Muriel Hele; a Feathery-footed Owl (*Athene plumipes*), a Black and White Jackdaw (*Corvus dauirica*) from Newchang, South Mantchuria, presented by M. J. De La Touche; two Indian White-Eyes (*Zosterops palpebrosus*) from India, a Yellow-winged Sugar-Bird (*Cœreba cyanea* ♂) from Brazil, a Dufresne's Waxbill (*Estrelda dufresnii*) from South Africa, six Vulturine Guinea Fowls (*Numida vulturina*) from East Africa, deposited; a Plumbeous Fish-Eagle (*Polioaëtus plumbeus*) from North-west India, two Golden-headed Parrakeets (*Cyanorhamphus auriceps*) from New Zealand, a Green-winged Dove (*Chalcophaps indica* ♀) from India, purchased; two Emus (*Dromæus novæ-hollandiæ*), received in exchange; a Yak (*Poëphagus grunniens* ♂), a Viscacha (*Lagostomus trichodactylus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on July 10 = 17h. 15m. 5s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4355	—	—	17 55 41	−23 2
(2) α Herculis	3·1-3·9	Orange.	17 9 38	+14 31
(3) β Draconis	3	Yellow.	17 28 0	+52 23
(4) ζ Draconis	3	Bluish-white.	17 8 30	+65 51
(5) 205 Schj.	8	Very red.	17 38 29	−18 37
(6) R Scuti	Var.	Red.	18 41 36	− 5 50

Remarks.

(1) Unfortunately this interesting object only attains a low altitude in this country, but it is quite possible that there may be some nights on which spectroscopic observations may be made. It is the object known as the "Trifid Nebula," which is thus described in the General Catalogue:—"A very remarkable object; very bright; very large; trifid; double-star involved." For a further description observers may refer to Herschel's "Outlines." The spectrum was recorded as "continuous" by Captain Herschel in 1868, but in the same year it was observed by Prof. Winlock at Harvard College, and found to contain bright lines. This observer records: "Spectrum of the multiple star continuous, with many bright lines and some bands; one end of spectrum at λ 4280± . . . one bright line seen by C. S. Peirce at λ 4980±." I am not aware that any further observations of the spectrum have been made, but these observations should certainly be repeated with as large an aperture as possible. There can be little doubt that the line near λ 4980 is really the chief nebula line at λ 500. The appearance of bands is especially interesting, as indicating that only a relatively low temperature can be in question.

(2) The spectrum of α Herculis is probably well known to everyone who possesses a telescope and spectroscope. It is a very beautiful one of Group II., all the bands being very wide and dark, giving an appearance of alternating bright and dark bands. From the observations of Prof. Lockyer, Mr. Maunder, and myself, there can now be little doubt that we have here to deal with a mixed spectrum of bright carbon flutings and dark metallic ones. One bright band in the green is coincident with the chief carbon band, and has, moreover, the same appearance. The measures of the dark bands in the green and yellow by Vogel and Dunér show close coincidences with the flutings of manganese (λ 558 and 586) and lead (λ 546), and I have confirmed these by direct comparisons. The principal object in inserting the star in this column is to remind observers that this is a good opportunity for them to demonstrate for themselves that in stars of this type we are dealing with cometary conditions, as indicated by the carbon radiation.

(3 and 4) These stars have spectra of the solar type and of Group IV. respectively (Gothard).

(5) Dunér describes the spectrum of this star as one of Group VI., in three zones, of which the green is the brightest. He states that the spectrum is rather feebly developed, but it is not clear whether this is due to the faintness of the star, or that the bands are narrow as compared with other stars of the group. If the latter, the star may be one of the long-required connecting links between stars of this group and stars of the solar type.

(6) The spectrum of this variable does not appear to have been recorded, although its magnitude at maximum is about 5. The minimum is irregular, 6·0–8·5, and the period, according to Schmidt, is about 168 days. There will be a maximum about July 14.

A. FOWLER.

SECULAR INEQUALITIES IN THE MOON'S MOTION.—In the *Astronomical Journal* for June 20, Prof. J. N. Stockwell contributes the abstract of a discussion of the problem of the secular variation of the motion of the moon's perigee and node. The value found for the secular variation of the mean longitude of the moon's node does not differ very materially from that found by Laplace and subsequent investigators. But it is otherwise with the secular equation of the motion of the moon's perigee; and if the value Prof. Stockwell has obtained for the secular motion of the moon's perigee is nearly correct, the value found by Laplace and his immediate successors cannot be regarded even as a first approximation to the value of that motion.

If the mean longitude of the moon's perigee be denoted by ω, and the number of centuries from a given epoch by i, the variation $\Delta\omega$ of the mean longitude of the perigee at any number of centuries from the epoch are quoted by Airy as follows:—

	$\Delta\omega$
	″
Laplace	$-30''\cdot55i^2$
Börg and Burckhardt	$-29\cdot98i^2$
Damoiseau	$-39\cdot70i^2$
Plana	$-40\cdot23i^2$
Hansen	$-39\cdot18i^2$
Hansen	$-36\cdot31i^2$.

Notwithstanding this agreement of the results of other investigators, Prof. Stockwell has found, by direct calculation, that $\Delta\omega$ is very nearly expressed by the formula

$$\Delta\omega = +15''\cdot61i^2;$$

and since the motion of the perigee is direct, it follows that this motion is *accelerated* instead of being *retarded* from age to age, as has been hitherto supposed. The application of the result to the discussion of some ancient eclipses is reserved for a future communication.

ANNULAR ECLIPSE OF JUNE 17.—The current number of the *Comptes rendus* contains a letter from M. A. de la Baume Pluvinel to M. Janssen, respecting his observations at Canea. Photographs of the annular and partial phases were obtained, and will be of service in determining the diameters of the sun and moon. M. Pluvinel also finds that there is no difference between photographs of the spectrum of the edge of the sun during the annular phase and the ordinary solar spectrum. It is interesting to note that during the eclipse the temperature fell from 33°·4 to 27°·4 C.

THE ETHNOLOGY OF THE GAMBIA REGION.

THE Governor of the Gambia, in his last Report, devotes a long section to an account of the African tribes connected with that settlement, of which the following is a brief summary:—

Mandingoes.—The head-quarters of this extensive and powerful race lie in the mountainous district near the sources of the Niger and the Gambia, extending as far as Kong. From this region they overran the surrounding country westward to Bambouk, and still pushed on, until the banks of the Gambia, as far as the sea, more or less, fell under their sway. At the present moment the principal countries on the north bank of the river are occupied mostly by Mandingoes, and the dominant tribes in Combo, on the south bank, are also of the same race, though the heathen Jolas in the bordering Fogni country are able to hold their own against them. They practically control the trade of the lower river. Three-fourths of the ground-nuts hitherto cultivated have been grown by them; the export of bees'-wax seems to be also dependent upon the Mandingoes, who bring it down from the interior of the Jola country. They also bring cattle and hides into the market, and cultivate cotton largely, which their women spin and weave into the country cloths which play

so conspicuous a part in the trade of the river. The Mandingo language is rich and musical, and susceptible of more variety of expression than the Jolof tongue, which, next after the Mandingo, is, perhaps, the most prevalent language. The latter adopt the decuple system of numeration, whereas the former only possess a quinquennial period. The Mandingoes, as a rule, are Mohammedans, though many are "Soninkees"; and in all their faith is permeated more or less with Fetishism. The term Soninkee is applied by Mohammedans to all people, irrespective of race, who drink spirits. Physically, they are in general a spare, athletic race, of medium height, often with aquiline features, but in contour always distinct from the typical Negro. In colour, they are not so dark as the Jolofs, but their hair is woolly. The laws in Mandingo towns are administered by "Alcalis," or Sumas, both terms having the same signification. The only difference is that the former is a kind of Prime Minister in a Mohammedan town, while the latter holds a similar office in a Soninkee town. Murder and adultery are punished by death. The sentence in the former case is carried out by killing in the same manner as the murder was committed, and in the latter the adulterer is usually killed with cutlasses. The adulteress suffers only whipping, and is cast out by her husband. Theft is punished by whipping, an instrument something similar to the "cat" being used for the purpose. Slander and disrespect to parents or the aged are punished by fine, which goes to the Alcali and headman of the town. Immorality as distinguished from adultery is almost unknown; but if practised and discovered would meet with the death penalty as in adultery. The Mandingoes still keep up a connection with their original country, and recognize a supreme authority in the ancient Mandingo kingdom, though the recognition is more sentimental than real, the distance being too great for any effective authority to be exercised.

Sereres.—This race occupies the neighbourhood of Joal, Seine, and Baol, to the north of the Gambia, and outside British jurisdiction. They are a distinct people, with a language having no affinity either to the Mandingo or Jolof. They are an independent and comparatively industrious race, cultivating largely both corn and rice; they also rear numerous cattle. They seldom buy cotton goods, and have no craving for luxuries of any description. Their wardrobe never consists of more than two *pagns* or country cloths. During the dry season many Serere youths come to Bathurst to work as labourers for about three months, their ambition being satisfied when they have earned sufficient to buy a trade musket, a knife, a wooden box, and a few minor articles, such as iron bars, iron pots, raw cotton, &c. Others at times come in with small canoes, and cut firewood for the Bathurst market, and also do a little fishing. In religion the Sereres are infidels, and, except in a few instances, have hitherto resisted all attempts to convert them to Islamism. They recognize a Supreme Being, but he is only invoked in case of hostile invasion, a fashion which has doubtless been borrowed from the Mohammedans. The king of Seine, who is the ruler of the Serere nation, keeps one Marabout attached to his person for the express purpose, but his services are never put into requisition on any other occasion. Physically they are a fine, well-grown race, with not unpleasant features, their complexion as a rule being of a deep black. As with the Mandingoes, murder and adultery are punished with death; shooting or decapitation, according to the decree of the king, being the means adopted. Immorality is treated in a more lenient fashion, and resolves itself into a question of money. It is stated by persons who know the customs of both tribes well that the Mandingoes and Sereres frequently condone the offence of adultery if the male culprit is rich enough to satisfy the outraged honour of the husband, and moreover from the necessity of extreme caution that the wives resort to various cunning devices in order to deceive their husbands. The virtue of these communities is therefore more apparent than real. Each Serere man is permitted by custom to have ten wives, but indulgence in a greater number is regarded as a pardonable folly. Theft is punished in a very drastic manner. The thief has the whole of his goods confiscated and handed over to the victim of the robbery. The primitive quinquennial period in reckoning is adopted by the Sereres, as is the case with the Jolofs.

Nominkas.—This race occupies the region known as the kingdom of Nuomi or Barra. Formerly Barra was the most important of all the kingdoms of the Gambia, owing to the number and strength of the war canoes controlled by the king. The present Nominkas appear to be divided into two sections, named respectively the Nomibartokas (meaning those living at the entrance of the river) and the Nomibantokas (meaning those living more within the river). The former occupy the region between Jonwar and Jinneck, and the latter live between the towns of Essow and Jooroonko. The Nominkas are all Mandingoes, but the Nomibartokas live so near to the Sereres that they speak this language in addition to their own. The Nominkas communicate with Bathurst by means of large canoes, which some of them are very clever at making. These canoes will sometimes carry as much as three tons of ground nuts, of which they cultivate large quantities. In religion most of the Nominkas are now Mohammedans, though originally they were Soninkees. Their laws are similar to the Mandingoes, from whom they sprang.

Jolas.—The history of this primitive and extraordinary race is involved in much obscurity. No idea appears to exist among themselves in regard to their origin, and even tradition is silent except as to recent events in the chronicles of their country. Even under favourable circumstances, Jola intelligence is of such a low standard that it is not easy to acquire much reliable ethnological information from them. So far as it is possible to learn from the people themselves, the Jolas, or Fellups, have always occupied a region having for its eastern boundary Vintang Creek, following the course of that tributary, and extending as far south as the head waters of Cazamance, continuing along the north bank of that river to its mouth, and from thence extending to the limits of foreign Combo. The Banyans, Papels, Balantes, and Biafares, sometimes called Jolas, appear to be allied races. Durand, a former Governor of the Isle of St. Louis, in his voyage to Senegal, published in 1805, gives some interesting details of these people, and the extensive Portuguese establishments which then existed at various stations in Vintang Creek and the Cazamance. He remarks that both banks of the latter river "are inhabited by savage and cruel Fellups, who will not hold any communication with the whites, and are always at war with their neighbours." Those, however, who resided in the neighbourhood of the Gambia, appear to have shown different characteristics, for in writing of the town of Bintan (Vintang), the same author says:—"The negro inhabitants of this part are Felups, they speak a language peculiar to themselves, and are idolaters. . . . Those of Bintan, or its environs, who are occupied in commerce, are gentle, frank, and civilized; they like strangers, are always ready to render them service, and are candid and honest in their commercial dealings." Vintang Creek, once an important trading district, producing large quantities of wax, hides, and ivory, is now all but abandoned, and the people content themselves with the cultivation of sufficient rice and corn to supply the bare necessaries of life. They are decidedly an industrious race, and numbers of them come to Bathurst to obtain work as labourers, especially during the trade season. Vessels are laden almost entirely by Jola women, and the merchants would find it difficult to get on without them. Physically they are not an attractive-looking race, and both sexes wear little or no clothing. In their own country there is practically no government and no law; every man does as he chooses, and the most successful thief is considered the greatest man. There is no recognized punishment for murder or any other crime. Individual settlement is the only remedy, and the fittest is the survivor. Unlike the rule amongst most African races, there is absolutely no formality in regard to marriage, or what passes for marriage, amongst them. Natural selection is observed on both sides, and the pair, after having ascertained a reciprocity of sentiment, at once cohabit. No presents are made by the bridegroom, and the consent of parents is entirely ignored. They do not intermarry with any other race. There appear to be three distinct languages spoken by the Jolas, having no affinity to those of the contiguous tribes, and but little resemblance to each other. The vocabulary appears to be poor, as might be expected in the case of a people with so few wants. The Jolas do not count beyond ten, and distinct terms are used only up to five, as in all the tribes noticed, except the Mandingoes. Beyond ten the counting becomes pantomimic, the people using both hands and feet to represent higher numbers. Pieces of stick are also employed for the same purpose. The Jolas, whether from persecution, or for some other reason, have always been an isolated race, and have shunned contact with their neighbours. In spite of the proselytizing nature of the powerful Mandingoes, they have utterly failed to introduce Mohammedanism, and the Portuguese appear to have been equally unsuccessful in establishing the Roman Catholic religion.

Jolofs.—Although "Jolof" is a word very frequently used in Bathurst, and most of the inhabitants speak that language, yet, as a matter of fact, very few of the genuine race are to be found in it. The habitat of the Jolofs is in the adjoining French colony of Senegal. The Jolofs proper are stated to be a handsome race; they are proud, and exceedingly vain, claiming for themselves a very ancient descent. The women are inordinately fond of gay apparel and personal adornments of every description. They frequently pierce the ear along the entire edge with a series of holes, so that this feature may be, as far as possible, loaded with ornamentation. The wool is pulled out to its extreme length and plaited into thin strips, which hang from the head, giving a peculiar character to these natives. Of their moral character report speaks very unfavourably, mendacity, deceit, and licentiousness being prominent characteristics of this people. In religion they are fervent Mohammedans; they rarely intermarry with any other race, but are extremely sensitive to any mishap in this direction. The Jolof language is expressive, and has received considerable attention from philologists, more than one grammar having been published. Golberry, who gives a vocabulary of the Jolof language, pertinently comments upon the curious fact that in spite of the contiguity of the Jolofs to the Moors, who adopt the Arabic system of numeration, the former should have persistently adhered to the method of reckoning on one hand only, instead of on both. It is a curious and perplexing circumstance that the Mandingoes, who are an inland people, and probably came into contact with more enlightened races at a later period than the tribes nearer the coast, should be in advance of all the other races in this portion of West Africa in their system of counting. The question whether this method originated with the language, or has been acquired at a later period of their history, must be left for philologists to settle. The Mandingoes, however, have always been great traders, and it is possible that their instincts taught them at an early stage the advantages of a system based on ten fingers instead of five.

Salum Salums.—These are neighbours of the Sereres, and through intermarriage their language is a mixture of Jolof and Serere. In religion they are partly Marabouts and Soninkees. The former frequently take wives from the latter, but no Marabout would give his daughter to a Soninkee unless to a king or a prince, and that reluctantly.

Lowbeys.—This race may be described as the gypsies of North-West Africa. It is almost impossible to obtain any certain information in regard to their history. They wander about from place to place, but have no settled country. There can be no doubt that they are practically the same race as the Foulahs, though for some reason they have become detached from them. Those seen by the Governor were decidely better looking than the average Negro, resembling the Foulahs, though of a darker complexion. They confine themselves almost exclusively to the making of the various wooden utensils in use by natives generally, and the manufacture of canoes. They settle temporarily with any tribe but never intermarry with another race, thus preserving the type of feature which obviously separates them from their human surroundings. In religion most of them are pagans, though a few profess Islamism. They have no laws of their own, but are guided by those of the people with whom they are for the time being located. In case of war happening, they very sensibly remove at once to a district where there is peace. The Foulahs and Toocalores, to whom allusion is made below, are practically the same race. Little need be said of them, as the former are a well-known race, and many travellers have noted their unusual lightness of complexion. Dr. Goulsbury, in his report on the Upper Gambia Expedition, gives a concise history of this people. Their capital is Timbo in the Futa Jallon country. The Toocalores reside principally in the Futa Toro country in Senegal, but from having intermixed with other races they are darker in colour. They are a warlike people, and at times are troublesome to our neighbours the French. An appendix to the report contains a vocabulary of common words and expressions used in the Mandingo, Jolof, Serere, Jola, and Foulah languages, all of which are spoken within a comparatively small radius of the Gambia. "No one can fail to be struck with the marked differences in the word forms of the various languages, though Mr. Robert Cust, in his valuable work, 'The Modern Languages of Africa,' classes all except the Foulah in one group, which he styles the northern section of the Atlantic sub-group, and which extends from the River Senegal to Cape Mount. It is difficult, however, for any but a trained philologist to detect wherein the relationship lies, or how such radical distinctions could exist and be preserved in the languages of races living in close proximity to each other. The Jolas especially offer a very curious problem to the ethnologist; it is not probable that they were ever an interior race which has been pushed gradually by stronger neighbours to the sea, and it is somewhat extraordinary that they should have been able hitherto to withstand the power of the conquering Mandingo, and to maintain their individuality. It is true they have always been a savage and intractable people, but in point of numbers their weakness would seem to mark them out as an easy prey to the invaders. This, however, is far from being the case, and there is but little of the Jola country in the hands of strangers."

SEEDLING SUGAR-CANES.

THE Government of Barbadoes has issued a valuable Report bearing on seedling sugar-canes. It records the results obtained by Prof. J. B. Harrison and Mr. J. R. Bovell on the experimental fields at Dodds Reformatory in 1889. As the subject is one of great importance to the cane industry, the following extracts may be read with interest. We may note that a paper describing the fruit of the sugar-cane was lately read before the Linnean Society by Mr. D. Morris, and that seedling canes are growing at Kew.

"In our Report for 1888 we briefly alluded, for the purpose of insuring priority, to the fact that we had succeeded in obtaining seedlings of the sugar-cane.

"That the sugar-cane could not produce fertile seeds has been for many years regarded by botanical authorities as a proved and accepted fact, whilst very many of the older planters here believed that the canes could produce fertile seed.

"Attention here was first strongly directed to this point in 1859 by the Hon. J. W. Parris, who succeeded, at his estate, Highlands, in St. Thomas's parish, in rearing successfully self-sown seedlings. . . .

"Mr. Parris has recently stated to us that he finally succeeded in planting four and a half acres with canes raised from these original seedlings, and that he estimated their yield of sugar at over four hogsheads to the acre. He, however, from certain objectionable characteristics which arose in the canes, finally abandoned their cultivation, and did not again turn his attention to the subject. In order to test the truth of Mr. Parris's discovery of cane seedlings, several persons here attempted to raise them from the cane arrows. This was done successfully by Mr. Carter, of Bridge Cot, and by Mr. J. Wiltshire Clarke, neither of whom, however, appeared to have attached much importance to their results. At another time Mr. T. Clarke, of Cane Field, discovered cane seedlings growing from a fallen cane arrow, but did not succeed in raising them, and Mr. E. S. Sisnett found some cane seeds growing in Christ Church about the year 1861; these were allowed to grow amongst canes that were planted in the usual way, but as they were very small and thin when they reached maturity they were destroyed. In this last case the seeds appear to have come from the Bourbon canes. Next we find that the late Mr. W. Drumm paid much attention to this subject and wrote several letters to the *Sugar Cane* upon it. He, however, stated to us in March 1884 that, whilst he had repeatedly obtained cane seed, he had never succeeded in raising canes from it, and that he believed the various instances we have mentioned to be errors of observation.

"At Dodds the cultivation of the different varieties of canes in large numbers and side by side has placed us in a specially favourable condition for examining into this question. In January 1888, Mr. J. B. Pilgrim, one of the overseers at Dodds, reported to us that in the neighbourhood of one of the experimental fields he noticed that certain fine grasses were springing up, and we found at intervals from then to the middle of March similar seedlings. These were found not only on the surface of the field, but also growing in the bottom of a somewhat deep drain which had been recently dug. Much difficulty was experienced in preserving these seedlings, as they were exceedingly sensitive to the effects of exposure to the sun or wind. In June 1888 the seedlings which had survived were transplanted, giving us about 60 plants. Certain of them were dug up with great care, and placed in water until the soil crumbled away from their roots, and were carefully examined for any traces of cane

that might be on the roots. Nothing could be detected, and we were strengthened in an opinion that they were true seedling canes by the very great difference in their mode of growth from that of canes growing from the eyes of canes. A few months later we found that there were several distinct varieties amongst them. In December 1888 we examined them with great care, and grouped them into ten groups according to their most strongly marked characteristics, and found that in many of our groups thus formed the canes graduated from one group into another. Many of these canes exhibited some of the characteristics of certain of our varieties, together with the characteristics of other varieties, but in some cases we could not even form any opinion as to their parentage, as they differed completely from any canes we had ever seen. During the latter stages of their growth these canes were examined by many planters and sugar chemists, all of whom were particularly struck with the amount of variation they exhibited and with the fact that certain of them were entirely different from any canes they had previously seen. The canes, as grouped, were replanted in the usual manner, and are now in course of experimental cultivation. The remaining canes were reaped on March 8, 1889, and fifty plants yielded 307 pounds of cane tops and 1626 pounds of canes, which gave 61 per cent. of juice of a density of 10°·6 Beaumé, containing 1·629 pounds of sucrose and 0·090 pounds of glucose in the imperial gallon. The following are the compositions of the canes, cane-juice, and megass:—

	Canes.	Cane-juice.	Megass.
Water	68·11	81·18	48·20
Sucrose	12·62	15·13	8·70
Glucose	0·69	0·83	0·48
Ash	0·47	0·30	0·75
Albuminoids	0·33	0·17	0·59
Fibre	15·44	—	39·60
Organic matters	2·34	2·39	1·68
	100·00	100·00	100·00

"In order to definitely settle the question of whether the sugar-cane produced fertile seed, from the middle of December 1888 to that of February 1889 most careful search was made through the fields for growing seedlings and for arrows containing fertile seed. The search for both of these proved successful, but only on the fields in which the varieties were growing and on which, as pointed out by us in our 1888 Report, the conditions for fertilization are most favourable. The seedlings, as found, were transplanted into boxes, but, on account of the unfavourable climatic conditions, great difficulty was experienced in preserving them: on one occasion an accidental exposure to the sun for about three hours destroyed five out of seven contained in the exposed box. One seedling was found attached to a portion of cane arrow which had fallen in a damp and sheltered position. The portions of cane arrows found which apparently contained fertile seed were collected, the apparent seeds carefully separated from the spikelets of the panicles and sown at intervals, commencing on January 12. Ten days after, some of the seeds were seen to be germinating, and certain of them were removed and preserved as microscopic objects. Of the apparent seeds, less than 5 per cent. germinated, and not more than one-fourth of the germinated ones finally survived.

"As the self-sown seedlings and those raised from the seeds by ourselves reached a sufficiently advanced stage of growth (the exceedingly slow growth of the seedlings at an early time is most marked, a point which in certain previous researches may have prevented the attainment of complete proof of the fact that the sugar-cane produces fertile seed, and in which mode of growth the seedlings strikingly differ from the rapid growth of canes from the buds) were, similarly to the seedlings of 1888, transplanted into the field, and are now in course of experimental cultivation.

"As far as our experience at present shows, the conditions most favourable for the production of fertile seed by the sugar-cane are found in the cultivation of varieties side by side and in comparatively large numbers, although from observations recently made, apparently fertilized ovules are to be found from time to time upon arrows of Bourbon canes growing by themselves. To secure the germination of the seeds, it is necessary to sow them soon after the arrow ripens, under similar conditions to those necessary with the seeds of other of the Gramineæ of low germinating power.

"The fertile seeds inclosed in the glumes are long and narrow, being from 3 to 4 millimetres in length and 0·65 to 0·70 millimetres in breadth, and terminate in a beard from 6 to 8 millimetres long."

MUSICAL SCIENCE.[1]

THE object of this little pamphlet is one with which musical students are tolerably familiar. The author complains that the science of acoustics, although now well advanced, is unable to explain the actual structure of musical compositions, or to account for their effect on the mind. Many writers have made the same complaint, and have endeavoured, each according to his own fancy, to "account for" everything by some particular system of his own.

Now, it happens that some quarter of a century ago a person named Helmholtz wrote a great book with the express object of explaining this difficulty. He showed, about as conclusively as anything can be shown, that, although physical science has furnished an intelligible basis on which the musical art is founded, it goes but a very little way in explaining practical musical composition, this being guided chiefly by the æsthetic instincts and the artistic feelings of the best composers, with which physical science can have very little to do.

One would have thought that such a doctrine would be hailed with satisfaction by musicians, as exalting and ennobling the share of art in the generation of high-class music. But, strange to say, it is the musicians who chiefly dispute it, and who would wish to substitute for the heaven-born gift the dry process of scientific deduction.

Our author is of this opinion. He tells us that if by science we are to understand a thorough rational understanding of any subject, musical science has not yet been discovered; it waits still its Columbus, or its Galileo, or its Cuvier.

This may be in a certain sense true, but the science wanted for the purpose is not *physical* science. We know already pretty well all that physical science can tell us about music; but there is a science much deeper—namely, that which would investigate the general effect produced by music on the mind, as depending on its composition and style. This is the *psychology* of music, an abstruse branch of æsthetics, and it is this that must tell us, if it can, how music has attained its present power over the feelings and the emotions of mankind. It is only lately that attention has been called to this by competent writers; what is popularly said or sung about it has seldom any serious meaning.

The idea promulgated in this pamphlet is that all the mysteries of the art may be explained on the principles of *rhythm*—not, as usually understood, having to do with time and measure and accent and so on, but in a more hidden application to the generation of sounds. The system is not completely elaborated, and it is not possible to do more here than give a very general notion of it. The first six chapters treat of rhythms in general; and the author gives a drawing of a machine for illustrating them. This consists of a series of "Savart" ratchet wheels, which, having different numbers of teeth, can give rise to various rhythmic combinations of their beats. He then deduces "laws" from the consideration of these, of which the following are some specimens:—

"When we listen to a series of isochronous blows, we perceive them at once in binary rhythm, and we therefore call this perception *spontaneous*, *natural*, and *instinctive*.

"We cannot perceive a series of isochronous blows in ternary rhythm, except with the concurrence of the will; hence we call this perception *voluntary*."

These are simple fundamental laws; the following are more complicated ones:—

"Whatever is the number of teeth of a wheel, and the velocity at which it revolves, there is always the spontaneous perception of the isochronous series in binary rhythm.

"If, to a series perceived in binary rhythm, we cause another to follow, which has with it any ratio whatever represented by r, this will be at once perceived in the same ratio r, which proves that the brain is endowed with the faculty of comparison.

"In any association whatever of two series of different rhythms, there is the production of a forced perception which compels the immediate perception of the two rhythms."

[1] "Musiconomia: Leggi Fondamentali della Scienza Musicale." By Dr. Primo Crotti, Professor of the History of Music in the Royal Conservatory of Parma. (Parma, 1890.)

In chapter iv. he explains a "physiological hypothesis," that the natural impression given by binary rhythm arises probably from the naturally symmetrical structure of the human body, and the binary action of its functions, such as breathing and the beating of the heart, whereas a ternary rhythmic motion seems something heterogeneous and unnatural. In chapter v. he discusses the effects of rhythms on our organism, simple or natural rhythms giving an agreeable impression, and unnatural or complicated rhythms giving one of a contrary description. Then follows a long chapter of formulæ and complicated arithmetical statements of rhythmical combinations of various kinds.

These remarks, on rhythms generally, occupy two-thirds of the pamphlet; the remaining third is intended to show how they may be applied to the nature and effects of musical sounds. Chapter vii. contains a description of the major musical scale as harmonically deduced by the aid of the monochord; and after that we begin to get a glimpse, though obscurely, of the nature of the general argument. The following extracts may give an idea of it:—

"The only sounds of the scale which are in binary rhythm are the first, 1 : 1, and the last, 1 : 2; and these are in fact the only ones which imply rest. The fifth, 2 : 3, is constituted by a ternary rhythm, and is, in fact, the sound of greatest motion which is contained in the scale. This most powerful motive action gives to this sound the greatest tendency towards the sounds of rest, authorizing it to fall directly on them, however distant from it.

"The ratio 4 : 5, which represents the major third, is constituted by a quinary rhythm—a rhythm of semi-motion which has such an action that while it makes us feel faintly the need to pass to the fundamental, it may almost supply it coming after the fifth."

Thus we arrive at the kernel of the theory, which appears to be that the effects of different combinations of rhythmical blows or noises are assumed to be applicable to the vibrations causing musical sounds, and to account for the effects of such sounds in an emotional point of view. It is something akin to the old Euler doctrine of the "simplicity of ratios," but it professes to be more comprehensive.

It is not carried out very far in this book, but the author promises that if he lives long enough, and has sufficient means, he will complete it in a larger treatise. Then, perhaps, we shall see how it will explain the construction of "Israel in Egypt," Haydn's Quartettes, and Beethoven's Ninth Symphony.

THE MUSEUMS ASSOCIATION.

THE first annual meeting of the Museums Association was held in Liverpool on June 17, 18, and 19, under the presidency of the Rev. H. H. Higgins, M.A. Liverpool was represented by the President, Mr. J. T. Moore, Mr. R. Paden, Mr. J. Chard, Mr. P. Cowell, Mr. H. A. Tobias, and a number of other gentlemen. In addition to the home contingent, the following were present:—Mr. F. W. Rudler, Mr. R. J. Howard, Mr. R. Ashton (Blackburn); Mr. J. Vicars, Mr. J. J. Ogle (Bootle); Mr. W. W. Midgley (Bolton); Mr. Butler Wood (Bradford); Mr. John Storrie (Cardiff); Mr. Montagu Browne (Leicester); Mr. C. G. Virgo (Manchester); Mr. T. J. George (Northampton); Mr. J. W. Carr (Nottingham); Mr. R. Howse (Newcastle); Prof. Boyd Dawkins, Mr. W. E. Hoyle (Owens College); Major Plant (Salford); Alderman Brittain, Mr. E. Howarth (Sheffield); Lieutenant-Colonel Turner, Mr. John Tym (Stockport); Mr. Robert Cameron, Mr. J. M. Bowley (Sunderland); Mr. L. Greening, Mr. H. Roberts, Mr. F. W. Moncks, Mr. C. Madeley (Warrington); Mr. H. M. Platnauer (York).

The proceedings were opened by Mr. J. T. Moore, as Mr. S. W. North, chairman at the last meeting (held in York), was unavoidably absent. The Rev. H. H. Higgins gave his presidential address, and the following papers were read and discussed:—"On Museum organization and arrangement," by Prof. W. Boyd Dawkins, F.R.S.; "Suggestions for aid in the determination of natural history specimens in Museums," by Mr. F. W. Rudler; "A new method of mounting Invertebrates for Museum and lecture purposes," by Dr. H. C. Sorby, F.R.S.; "Notes on the Liverpool Free Public Museum," by Mr. T. J. Moore; "Circulating school cabinets for elementary schools," by Mr. John Chard (Assistant in the Liverpool Museum); "The best means of making Museums attractive to the public," by Mr. R. Cameron; "A plea for local geological models," by Mr. T. J. Moore; "Museum cases and Museum visitors," by Mr. E. Howarth; "Notes on the Moscow Museum," by Mr. Willoughby Gardner; "Winter evening lectures in Museums," by Mr. R. Paden (Assistant in the Liverpool Museum).

Some very pleasant expeditions were made, thanks to the untiring energy of the local Secretary, Mr. H. A. Tobias, who was ably seconded by Mr. Cowell and Mr. McMillan. The members of the Association were most hospitably received; they were entertained at lunch by his worship the Mayor, and received invitations to a *soirée* of the Library, Museum, and Arts Committee, and to a magnificent *conversazione* given by the Japanese Consul, Mr. James L. Bowes.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Prof. Elias Loomis: a memorial address prepared by H. A. Newton at the request of the President and Fellows of Yale College.—The magnetic field in the Jefferson Physical Laboratory, Part II., by R. W. Willson. In the February number of the *Journal* the author gave some observations of the variations of the horizontal intensity in different parts of the Jefferson Physical Laboratory in 1886–87, and upon the disturbance in the magnetic field produced by the presence of iron steam pipes and other iron masses. He now finds from extended observations that brickwork produces a great disturbance of the magnetic field, and thinks, therefore, that in general it would be safer to make exclusive use of wood for buildings and piers intended for refined magnetic measurements.—The electrical resistance of the alloys of ferro-manganese and copper (from determinations made by Mr. B. H. Blood), by Edward L. Nichols. The observations show that ferro-manganese-copper alloys decrease in electrical resistance each time they are subjected to a change of temperature. In one case an alloy containing 80·82 per cent. of copper and 19·12 per cent. of ferro-manganese, was hard drawn in the process of obtaining a strip suitable for measurement. Its specific resistance at 20°, referred to pure copper as unity, was 30·38; this resistance gradually diminished as the strip was repeatedly heated to 100° and cooled to 20°, until after seven such heatings it had fallen to 30·072. The effect of successive annealings upon the resistance of a number of alloys is also described.—Fluid volume and its relation to pressure and temperature, by C. Barus. The paper contains the introductory part of a series of experiments on the compressibility of liquids, in progress at the Physical Laboratory of the U.S. Geological Survey. Taking the results from 0° to 185° as a whole, it follows that if with the observed thermal expansion compressibility be supposed to increase inversely as the first power of the *pressure binomial* ($A + p$, where A is constant), then temperature and pressure must vary linearly to maintain constancy of volume.—On hamlinite, a new rhombohedral mineral from the herderite locality at Stoneham, Me., by W. E. Hidden and S. L. Penfield.—On a large spring-balance electrometer for measuring (before an audience) specific inductive capacities and potentials, by Alfred M. Mayer. The chief characteristic of the excellent piece of apparatus described is that it shows *directly*, and not inferentially, that different dielectrics transmit the force of electricity in different degrees.—Notice of new Tertiary mammals, by O. C. Marsh.

THE *American Meteorological Journal* for June contains:—An article on the distribution of cloud over the globe, specially prepared by M. L. Teisserenc de Bort from a former paper on this subject (NATURE, vol. xxxvi. p. 15), with diagrams of mean isonephs for March, which is the clearest month over the globe, and for July, which, on the whole, is a cloudy month, and also with figures showing the appearance of the cloud bands on the earth, compared with other planets having atmospheres.—Is the diurnal variation of the magnetic needle a meteorological phenomenon?, by Prof. R. Owen. The object of the paper is to show that our atmosphere is the medium influenced magnetically by the sun, in affecting the diurnal movement of the needle. The author thinks that the facts adduced may aid us in understanding why storms in the northern hemisphere rotate from right to left, and advance from lower to higher latitudes.—A translation of Dr. R. Assmann's paper on the climatological influence of influenza.—Report of the meeting of the New Eng-

land Meteorological Society on April 15. The chief subject of discussion was climatic changes, which were considered in two divisions: (*a*) Secular changes, introduced by Prof. W. M. Davis. He stated that secular variations have undoubtedly taken place, but we cannot give specific explanations of them. (*b*) Supposed recent changes, introduced by Prof. W. Upton. Several long series of observations were examined, and, while slight indications of periodicity were found, there was no trace of progressive change.—Trombes and tornadoes, by M. H. Faye (concluded from the May number).—Method of determining the direction of the wind by observation of the undulations at the margins of the disks of the heavenly bodies, especially the sun and moon, viewed through a telescope, by Don V. Ventosa, of the Madrid Observatory. The author states that there are always two points on the limb diametrically opposite, where the undulations travel tangentially to it and in the same direction, while in intermediate regions the waves appear more or less inclined to the limb. These motions indicate by their directions those of the wind which produces them.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—"On the Changes produced in the Circulation and Respiration by Increase of the Intracranial Pressure or Tension." By Walter Spencer, M.S., Assistant Surgeon to Westminster Hospital, and Victor Horsley, B.S., F.R.S.

The authors have made for some time the effect of an increase in intracranial pressure or tension the subject of an experimental inquiry, so far as the increase affects the circulation and respiration.

They conclude that the increase in intracranial pressure influences the circulation and respiration through the diminution in the physiological activity of the medulla which it causes.

The authors first give an historical *résumé* of the work of previous observers.

The following is a summary of the chief results obtained:—

I. *The Heart*.—A considerable increase of the intracranial tension was required to influence the heart; it became slowed and finally arrested. This happened more readily after respiration had ceased, and required a higher pressure to produce it when artificial respiration was employed, whilst division of both vagi nerves abolished any slowing or arrest. The arrest, when produced, continued permanently, unless the pressure was quickly removed, or artificial respiration employed, or the vagi divided. But if the pressure was maintained whilst artificial respiration enabled the heart to start again, then the cardio-inhibitory influence was gradually lost, so that the heart returned from being very slow to its normal rate, or increased beyond the latter until the rate became equal to that seen after division of the vagi. When the vagi were divided at this stage the rate of the heart did not alter.

The Blood Pressure.—A primary rise, small in the dog, larger in the monkey, was followed by a fall distinct from that produced by the slowing of the heart, and not necessarily accompanying it. When the heart started again the blood pressure rose, finally reaching the level seen after division of the vagi, so that no further rise took place when this was done. The power of producing a fall of blood pressure was easily lost. After division of the vagi the blood pressure was raised by increasing the intracranial tension and by artificial respiration, so that it could be maintained at a level between 300 and 400 mm. Hg for considerable periods.

Respiration.—This was likewise impaired and arrested. Its arrest reacted upon the heart and the blood pressure upon it, so that after the rise of blood pressure respiration occurred, even although a much higher intracranial tension was maintained than had been sufficient to arrest it when the blood pressure was lower.

II. By the direct application of pressure in the upper part of the 4th ventricle a slowing of the heart with a rise of blood pressure was caused, whilst respiration continued, so rapid as even to be nearly three times the rate of the heart in some cases. Pressure below the calamus scriptorius arrested the respiration without directly influencing the heart, whilst in the lower part of the 4th ventricle respiration was impeded or arrested along with a fall in blood pressure, and some slowing of the heart, followed by arrest, after the respiration had ceased.

"On the Alleged Slipping at the Boundary of a Liquid in Motion." By W. C. Dampier Whetham, B.A., Coutts Trotter Student of Trinity College, Cambridge. Communicated by J. J. Thomson, M.A., F.R.S., Cavendish Professor of Experimental Physics, Cambridge.

The experiments of Helmholtz and Piotrowski on the oscillations of a metal sphere suspended bifilarly, and filled with various liquids, gave finite values to the slipping coefficients. The theory of the flow of liquids through capillary tubes, applied to these results, show that such an effect would produce a marked change in the time of flow of a given volume of liquid. Poiseuille showed that for a glass tube there was no slip, and it follows that the flow through a gilt tube of about a millimetre in diameter should be twenty times as fast as through a glass one.

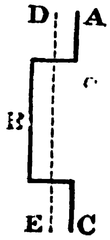
The time of flow of a given quantity of water through a glass tube was observed, and the interior of the tube was then silvered. The time was always the same for the glass and for the silver surface. The velocity of flow was varied within wide limits, and pushed near the point at which the flow ceases to be linear.

Other experiments were made on drawn copper tubes, which also agreed with Poiseuille's laws. Even when the interior surface was modified by cleaning with acids and alkalies, polishing with emery powder, coating with oil, or amalgamating with mercury, there was no change in the rate of flow. There is certainly no slip with substances which are wetted by the liquid.

Some preliminary experiments of Piotrowski on an oscillating glass flask, the interior of which was afterwards silvered, were then repeated, and it was shown that, when more precautions than Piotrowski took were used, the friction on the flask was the same, whether the surface was glass or silver.

Physical Society, June 20.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Prof. A. W. Worthington made a communication on the stretching of liquids. The three known methods by which this may be effected—viz. the barometer tube method, the centrifugal method, and the method of cooling—were described, and the precautions necessary in filling the tubes and in freeing the liquids from air discussed. With non-volatile liquids, such as sulphuric acid, the tubes are put in communication with a good pump, and before sealing, the liquid in the tube is kept at a higher temperature than that in the communicating vessel, in order that a stream of vapour may be passing outwards and carry with it any air liberated from the glass during the process of sealing. Before using tubes by the centrifugal method the author finds it advantageous to subject them to considerable "jarring" at intervals. This usually breaks the liquid column, and liberates a small bubble of air which may then be floated out. By repeating this many times, the adhesion of the liquid is greatly increased. With these precautions he had subjected water to a tension of 7·9 and sulphuric acid to one of 12 atmospheres. The cooling method of Berthelot (*Ann. de Chemie*, xxx., 1852) was then tried. In this method the liquid nearly fills a strong closed glass tube at a particular temperature. On slightly heating, it expands and fills the whole tube, any residual air being dissolved. On cooling again, the liquid remains extended, and still fills the tube until at last it lets go with a violent "click," and the bubble of residual air and vapour reappears. The tension of the liquids tested under these circumstances have usually been calculated from the relative change of volume on the assumption that the coefficient of extensibility is the same as that of compressibility. The author exhibited and described an apparatus by which the tension and the extension can be measured simultaneously. The tension is ascertained from the enlargement of the ellipsoidal bulb of a thermometer sealed into the containing vessel, and the extension calculated from the volume of the bubble after the click. The tension thermometer had been calibrated by internal pressure, and in determining the extension, correction is made for the change of volume of the apparatus. By this method he had subjected alcohol to a tension of 17 atmospheres, and found that the coefficient of extensibility is much less than that of compressibility. It is not clear what causes the liquid to let go of the glass, but it is found that the bubble can be caused to reappear by passing an electric current through a wire sealed in the capillary tube. Sir Wm. Thomson remarked that Prof. Worthington's paper was a curious commentary on the usual mathematical definition of "a liquid" as a substance which offered no resistance to being separated into parts. Speaking of freeing liquids from air, he said the beneficial effect of jarring could

easily be shown by tapping an ordinary "philosophical hammer"; separation of the column always leaves a bubble which can then be floated off. He had also found that, in freeing liquids from air by boiling, it was advantageous to have a long escape tube so that part of the liquid condenses and runs back.—Mr. C. V. Boys read a paper on the measurement of electromagnetic radiation by himself, Messrs. A. E. Briscoe and W. Watson. When Mr. Gregory described his new electric radiation meter on November 1, 1889, one of the authors said that the observed effect might be due to some cause other than expansion by heating, and that if it was a true heating effect it might be measured thermally. The present communication describes experiments undertaken to investigate the question. The first method employed was developed from the idea that if two fine wires be placed near together, and both act as resonators to a primary oscillator, the electrodynamic attraction caused by the electric currents up and down the wires, and the electrostatic repulsion between the charges on them, might result in the relative motion of the two wires. From theoretical considerations based on the assumption that the currents are harmonic in time and space, the authors inferred that the electrodynamic effect would preponderate at the middle of the wires, whilst the electrostatic repulsion would be greatest at the ends. To cause the attractions and repulsions to conspire in producing rotation, cranked resonators, A, B, C (see figure), were made; one was fixed, and the other suspended by a quartz fibre, to turn about a middle line, DE. These were inclosed in a glass vessel, and on starting the oscillator a turning movement was observed in a direction opposite to that expected. This motion was eventually traced to the electrostatic influence of the oscillator, for although the imperfectly conducting surface of the glass acted as a perfect screen from such action when the potentials of the oscillator were varied slowly, it did not do so for changes occurring about 500 million times per second. After adopting means to avoid this disturbance, and constructing lighter resonators, the experiments were repeated, with negative results. From the dimensions of the quartz-fibre used it was estimated that a force of 158 millionths of a grain could have been detected with certainty; this would have corresponded to about $\frac{1}{300}$ of an ampere in each resonator. It is hoped that by further increasing the sensitiveness of the apparatus, and using parabolic reflectors, the effect sought for may be detected. In the second method of attacking the subject, a Joule's dynamic air-thermometer was employed. This consisted of a glass tube with a partition along the middle extending nearly to the ends. If one side of the tube be warmed, convection currents circulate, and deflect an index placed in the steam. A small mirror suspended about one edge, and counterpoised, was used for an index, and was so sensitive that it was impossible to get the air still enough by any ordinary method of screening. However, by the ingenious device of putting the thermometer within a larger tube kept rotating by clockwork, the difficulties were surmounted. A doubled wire placed in one side of the thermometer served as resonator, and on starting the oscillator a large deflection resulted. A similar deflection was caused by applying about $\frac{1}{8}$ of a volt to the ends of the wire. This proved that the effect observed by Mr. Gregory is due to heating. The least rate of heating observable with the air thermometer was found to correspond to one calorie (gramme-water-Centigrade) per 24 hours in the whole tube, or 1 calorie per centimetre of wire in 103 days. Dr. Lodge asked Sir William Thomson whether, when electric pulses travel along parallel wires with the velocity of light, any action could exist between them, for two charged spheres travelling together at that velocity exert no mutual attraction or repulsion. In reply, Sir William said he was inclined to think Mr. Boys's treatment of the subjection was in the main correct, but it was quite possible that at such velocities the ordinary laws might be modified by the fact that the time taken for the force to be propagated from wire to wire is comparable with that required for the pulse to travel the whole length of the wire. As an example of the peculiar effects of rapid discharges, he said he had seen two copper wires which had been flattened against each other by lightning. Mr. Boys thought that in his resonators a condition analogous to stationary waves would exist, for the pulses are reflected from the ends. Dr. Lodge said he had that afternoon observed the action of parallel strips when Leyden-jar discharges were passed through them. The strips gave a kick at each discharge. Mr. Gregory mentioned that, in trying to increase the sensitiveness of his meter so as to measure the variation with distance, he had found that two resonators in proximity interfered with each other. He had, however, succeeded in increasing the sensibility about five-fold. Prof. Worthington asked if it was possible to measure the energy of the oscillator, and also whether the quantity caught by the resonator could be estimated from the solid angle it subtended at the source of energy, wherever that might be. Prof. Perry considered it easier to infer the energy of the source from that received by the resonator. Dr. Lodge said the energy of the source could be easily measured. The power radiated was enormous whilst it lasted, vastly exceeding that of tropical sunshine; and, if it could be made continuous, the apparatus would soon be red-hot. The energy radiated, he said, converges on the resonators, and hence the solid angle method of estimating the amount received would be erroneous. Moreover, the source was not at the oscillator, but at a quarter wave-length from it, and most of the energy returns to the oscillator; only a small fraction is splashed off and sent into space. Small oscillators radiate powerfully because the quarter wave-lengths are small; whereas the slow oscillators or alternators used commercially radiate very little of their energy. The exact law of variation of intensity of radiation with distance was rather complicated, but the theory had been completely worked out by Stokes in 1848. Mr. Blakesley thought the energy that returns to the oscillator would be available for subsequent radiations. Dr. Lodge pointed out that wires or other resonators placed within the quarter wave-length would intercept part of the returning energy.—Two communications—notes on secondary batteries, by Dr. Gladstone and Mr. Hibbert; and an easy rule for calculating approximately the self-induction of a coil, by Prof. J. Perry—were taken as read. In the first of these the authors show cause for believing that the beneficial effect produced by adding sodium sulphate to the ordinary electrolyte is due partly to its facilitating the reduction of lead sulphate and also to its power to diminish local action between the electrolyte and different parts of the lead plates. As regards the chemical actions which take place during the working of ordinary cells, they see no reason to doubt the view put forward by one of them in 1882, that the substance produced in the voltaic reaction is ordinary lead sulphate, $PbSO_4$. They also conclude that the high E.M.F. of a cell immediately after stopping the charging current is due to the inequality of acid strength near the two plates, and the gradual fall of E.M.F. is caused by the equalization of strength produced by diffusion.—Prof. Perry's rule relates to hollow cylindrical coils, and is expressed by the following formula:—



$$\text{L (in secohms)} = \frac{n^2a^2 \div 10^7}{1.844a + 3.1c + 3.5b};$$

where n = number of windings,
a = mean radius of winding in centimetres,
b = axial length,
c = radial depth of winding,

and b and c are less than $\frac{a}{2}$.

The time-constant of such a coil is given in terms of the volume of copper (V′) in cubic centimetres by

$$\frac{L}{R} = \frac{V' \div 1000}{0.728a \div 1.33c + 1.5b};$$

and the conditions for making this small are pointed out in the paper.—A paper by the Rev. T. Pelham Dale was postponed till next meeting.

Anthropological Institute, June 10.—Prof. Flower, C.B., F.R.S., Vice-President, in the chair.—The Chairman exhibited a "ula" or fetish brought by the Rev. L. O. Warner from the neighbourhood of Lake Nyassa.—Mr. Theodore Bent read a paper on the nomad tribes of Asia Minor. The paper referred in the first place to the heterogeneous mass of nationalities on and around the Cilician plain, but took only one point for discussion—namely, the religion of the Ausairee around Tarsus, identifying this cult with that of the Ali-ullah-hi of Northern Persia, and proving that most nomads, from the Mediterranean to the Caspian, belonged to this secret religion. The dogmas of the religion were set forth as obtained from three sources, namely: (1) account of the renegade Suleiman; (2) studies amongst the Ali-ullah-hi; (3) researches amongst the Ausairee of Tarsus.—The Rev. E. F. Wilson read a few notes on some North American Indians.—

In a paper entitled "A Contribution to a Scientific Phrenology," Mr. Bernard Hollander presented the result of further investigations into brain-functions—the first series of which has been published in the Journal of the Anthropological Institute of August 1889—showing again a striking similarity between modern experimental researches and the observations made by the founders of the phrenological doctrine. (*a*) The centre for visual perception and ideation [first occipital convolution]—considered by some physiologists to be the centre for the "concentration of attention"—corresponds with the localization of "concentrativeness," by Geo. Combe. (*b*) Mr. Herbert Spencer, who in the *Zoist*, vols. i. and ii., published his phrenological observations, considers the area, which Dr. Gall noted to be connected with visions and hallucinations, to be the centre for the revivification of ideas, which in its unnatural actions is accompanied by a difficulty in distinguishing revived impressions from real perceptions. The localization is the same as Dr. Ferrier's centre [12], the excitation of which causes such movements of eyeballs and head as are "essential to the revivification of ideas." (*c*) Excitation of the third and fourth external convolutions in jackals and cats is accompanied by retraction of the ear, a sudden spring or bound forward, opening of the mouth with vocalization and other signs of emotional expression, such as spitting and lashing the tail as if in rage. Dr. Gall located in the same area the "carnivorous instinct," termed "destructiveness" by his followers, and considered by Prof. Bain to be merely another name for the irascible emotion. Though the investigations are by no means finished, Mr. Hollander expressed the hope that an examination of his two communications to the Institute may induce men of science to reconsider the antiquated system of phrenology, which has hitherto failed to recommend itself to the scientific world.

Geological Society, June 18.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—The Borrowdale plumbago, its mode of occurrence and probable origin, by J. Postlethwaite.—Notes on the valley-gravels about Reading, with especial reference to the Palæolithic implements found therein, by O. A. Shrubsole. The following deposits containing implements are described:—A. *North of the Thames.* (i.) Gravel at Toot's Farm, Caversham; 235 feet above sea-level. (ii.) Clayey gravel by side of Henley Road, Caversham; 168 feet above sea level. (iii.) Subangular gravel at Shiplake; 200 feet above sea-level. B. *South of the Thames.* (i.) Gravel at Elm Lodge Estate, Reading; 197 feet above sea-level. (ii.) Gravel on disturbed beds at Redlands; 157 feet above sea-level. (iii.) Comminuted flinty gravel at Southern Hill; 223 feet above sea-level. (iv.) Gravel at Sonning Hill; 185 feet above sea-level. (v.) Gravel at Ruscombe, Twyford; 165–170 feet above sea-level. The author concludes that the highest gravels (235–280 feet above sea-level) do not, so far as is known, contain any traces of man, and that a considerable amount of valley-erosion occurred before the deposition of the earliest gravels which have furnished human relics. Further, he considers that the deposits indicate the occurrence of a severe climate at an early stage, and its recurrence at a later one, viz. during the deposition of the gravels found at a height of 197 feet and 144 feet respectively above the sea-level. He believes that many of the implements found in the lower levels at Reading have been derived from gravels of various dates and different levels, which have been swept away by denudation, and that this will account for the mixed character of the types of implements. After the reading of the paper, Mr. Monckton said he had noticed great variability of the gravels around Reading, and would like to learn whether it was possible to trace the subdivisions shown in the section of the pit at Grovelands for any distance laterally. Mr. Abbott could not understand from the section displayed that the Groveland gravel belonged to the Thames system. The author maintained that the variations could, to some extent, by traced laterally. The appearance of dip towards the Kennet in the section referred to by Mr. Abbott was misleading. He did not expect contemporaneous and identical valley-gravels to be discovered on the Oxford and Berks sides of the river in the way suggested. At the point in question the levels were very different.—The next meeting of the Society will be held on Wednesday, November 12, 1890.

Royal Microscopical Society, June 18.—Mr. Frank Crisp in the chair.—Mr. Mayall mentioned, in explanation of the delay in bringing forward the report of the new objective, that, before the Committee met officially to examine the objective, it had been agreed to support the report by the production of photo-micrographs of the various objects used as tests. They were, however, disappointed to find that the visual and actinic foci were not coincident, and at the request of Prof. Abbe the objective was returned to Jena. After a lapse of several weeks, Dr. Czapski replied that he had not found any trace of a "chemical" focus non-coincident with the visual focus, and the objective was again forwarded to London. The Committee then met, and the same fractured valve of *P. angulatum* was focussed accurately and then photographed, and it appeared quite sharp in the photograph. The transit of the objective from London to Jena had somehow got rid of the "chemical" focus. Unfortunately, the slide had become seriously deteriorated, so that the critical tests which they intended to photograph could no longer be tried. They were therefore compelled to await the arrival of another slide, which Dr. Van Heurck had most kindly sent, but which the Committee had not yet been able to examine.—In the absence of Mr. Pringle, the new photo-micrographic apparatus recently made to his instructions by Messrs. Swift and Son for the Royal Veterinary College, was described by Mr. Mayall.—Mr. E. M. Nelson exhibited upon the screen two photographs of the bordered pits of pine-wood. He thought these pictures showed clearly that the pits were of the nature of clack valves, and probably served the purpose of checking the downward pressure of fluid in the vascular system. He also showed some new photographs of diatoms × 1350, including one erratic form, which he proposed calling *Craspedodiscus punchbowlii*, from its resemblance to a punch-bowl.—Mr. Mayall gave a summary of the contents of a paper, by Dr. Charles E. West, of Brooklyn, on early binocular instruments.—Mr. Dowdeswell's paper, entitled "A Contribution to the Study of Yeast: Part I., Baker's Yeast," was read. Culture-tubes, containing specimens illustrative of the subject, were handed round for inspection.—Mr. C. D. Sherborn read some portions of a paper which had been prepared by himself, conjointly with Mr. H. W. Burrows and the Rev. G. Bailey, on the Foraminifera of the Red Chalk of Norfolk, Lincolnshire, and Yorkshire.

PARIS.

Academy of Sciences, June 30.—M. Hermite in the chair.—On the partial eclipse of the sun of June 17, by M. J. Janssen (see Our Astronomical Column).—On an attempt at oyster-culture carried on in the fish-pond of the Roscoff Laboratory, by M. de Lacaze-Duthiers.—On the photographic spectrum of Sirius, by Dr. Huggins. A new group of the ultra-violet series of lines is described, extending from λ 3199 to λ 3338.—On the application to great falls, in canals, of locks with oscillating liquid columns, and on a method of utilizing the automatic oscillating tube without its being blocked when the fall is considerably increased, by M. A. de Caligny.—On the residual charge of condensers, by M. E. Bouty. The author describes some experiments made with mica condensers. Among the results obtained are: (1) That a charge absorbed between the times θ and $\theta + t$ by a condenser which does not leak is identical with the residual charge liberated between θ and $\theta + t$ by the same condenser charged during a very long time. (2) This residual or absorbed charge is proportional to the electromotive force of the charging battery.—Researches on the application of the coefficient of optical rotation to determine the nature of the compounds which are produced by the action of malic acid on neutral tungstates of soda and potash, by M. D. Gernez. The experiments show: (1) That, both with salts of soda and potash, a regular increase of negative rotation occurs with solutions of increasing strength until a maximum of $-7° 7'$ is reached, when equal equivalents of the two bodies are used. (2) A diminution of the rotation with change of sign and a positive maximum of $+2° 42'$ for one equivalent of acid to two equivalents of the salt. (3) A diminution of the rotation with change of sign and a negative maximum of $-2°{\cdot}1$ when the solution contains one equivalent of acid to three equivalents of the salt.—On the action of titanium chloride on metals, by M. Lucien Lévy.—On the decomposition of rocks and the formation of arable land, by M. A. Muntz.—The author has found nitrifying micro-organisms universally distributed, even occurring on the bare rocks of mountain peaks, and attributes to them a considerable share in the work of breaking down rock-masses into soil.—On the development of the blastoderm in the isopodous Crustacea (*Porcellio scaber*, Latr.), by M. Louis Roule.—Crystallographic and optical properties of pyroxene obtained by means of superheated water, by M. A.

Lacroix. The conclusion is drawn that all its properties are sufficiently characteristic to identify artificial pyroxene with that of volcanic rocks.—The identity of composition of some sedimentary phosphates with apatite, by M. Henri Lasne. Phosphates from various sources and of different geological ages have been found to consist essentially of calcium fluophosphate of the same percentage composition as apatite, together with varying amounts of clay, calcium sulphate, &c.—On the reproduction of sillimanite and the mineralogical composition of porcelain, by M. W. Vernadsky. Kyanite and andalusite are transformed into sillimanite when raised to a white heat; the same mineral, or some body very like it, is shown by the author to be produced on heating together an intimate mixture of dry SiO_2 and dry Al_2O_3. He further proves that the products of decomposition by heat of topaz, dumortierite, and kaolin are composed in great part of the same substance, and that the crystalline portion of porcelain consists also of this mineral.—On the fauna of pyritic Ammonites of Djebel-Ouach, province of Constantine, by M. G. Sayn.—Craniectomy on a microcephalous subject, by M. Lannelongue. A remarkable operation on a female, aged four years, is described, resulting in a considerable amelioration of the condition of the patient.—On a new system of representing geographical relief, by M. Eugène Guillemin.

Berlin.

Physical Society, June 13.—Prof. Du Bois-Reymond, President, in the chair.—At the opening of the meeting, Prof. Schwalbe referred in the warmest terms to the loss the Society had sustained by the death of Director F. Gallenkamp, who had for many years acted as its Librarian.—Prof. Vogel spoke on photography in natural colours as attempted at first by Seebeck, then in succession by Becquerel, Niepce, St. Victor, Poitevin, Zenker, and most recently by a Hungarian named Verres. He exhibited a series of photographs in colours obtained by Verres, which, however, showed conclusively that he has not solved the problem, since, although the reds appear as red in the photographs, so also do the yellows and greens appear as red, and the blues as an undeterminate colour. These photographs, on the other hand, mark a distinct advance in colour-photography, since they are fixed, while those of Zenker, although more strikingly coloured, were not fixed. The speaker criticized Zenker's views on the mode of formation of a coloured photograph, and expressed his disbelief in the possibility of any *one* substance being so changed by rays of different wave-length as to emit, from various parts of itself, rays of exactly corresponding wave-length.—Prof. Kundt exhibited a spiral of bismuth, as employed by Dr. Lenand to demonstrate the influence of a magnetic field upon the electrical conductivity of this metal; he further showed by experiment how considerable this influence is, and pointed out that it provides a means of measuring the intensity of the field.—Prof. Lampe explained that some years ago he had announced to the Society that a problem on maximal attraction of a point dealt with by Gauss had been previously propounded and treated by Playfair. More recently he had found that even Playfair was not the first to deal with this problem, but that a partial solution had been obtained by De Saint Jacques in 1750.

Physiological Society, June 20.—Prof. Du Bois-Reymond, President, in the chair.—Dr. I. Munk gave a *résumé* of the present state of knowledge as to the absorption of fat. The fact that fats with a high melting-point, such as stearin, are not absorbed is usually adduced in support of the supposed importance of emulsification; on the other hand, some of the speaker's own experiments had shown that a small amount (5–7 per cent.) of this fat may be absorbed. In support of the saponification of fats he described some recent experiments made on the patient with a lymphatic fistula (Nature, vol. xli. p. 504) and on dogs. Thus, for instance, when spermaceti was administered to the patient after prolonged fasting, the lymph became cloudy and milky in the third or fourth hour of digestion. Analysis of the whole lymph secreted during thirteen hours showed that 15 per cent. of the spermaceti had passed into the lymph, not, however, in an unchanged condition, but as palmitin, showing that the spermaceti must have been decomposed in the alimentary canal, and that the palmitic acid of which it is partly composed must have become united with glycerin. He made further experiments with oleate of amyl-alcohol, hoping to verify the decomposition of this fat by observing that the animal exhibited symptoms of poisoning with amyl-alcohol: this was, in fact, observed. The above compound could not, owing to its pungent taste, be given in sufficiently large doses to the patient with the lymphatic fistula to be conclusive; but an analysis of the lymph secreted from the fourth to the twelfth hours showed that it contained, not the compound of oleic acid and amyl-alcohol, but olein—a further proof of its decomposition before absorption. So many difficulties stand in the way of the view that all fats are saponified before absorption, that the speaker considered the various points in connection with the process of fat absorption as still undetermined.—Prof. Ewald gave an account of the sudden death of a patient following upon the introduction of a flexible gastric sound; a subsequent *post-mortem* showed that the cause of death was rupture of an aortic aneurism. He then proposed as a subject for discussion the question as to whether the rise of blood-pressure which led to the rupture was due to the slight abdominal pressure or to some psychic excitation. The majority of those who joined in the discussion regarded the former as the causative factor of the rise of aortic blood-pressure.

Brussels.

Royal Academy of Sciences, May 6.—M. Stas in the chair.—The following communications were presented:—On the conditions of the act of chemical combination; modifications arising from the presence of inactive dissolvents; extract of a letter from M. Menschutkin, Professor of Chemistry at St. Petersburg, to M. Louis Henry. Prof. Menschutkin has studied the combination of $(C_2H_5)_3N$ with C_2H_5I in the presence of inactive dissolvents, for example, hydrocarbons, simple ethers, ketones, &c. The experiments show that such substances exercise a considerable influence on the velocity of combination, it being found that if 1 represents the constant of velocity of the reaction noted above in hexane, C_6H_{14}, this constant for the same combination in $CH_3—CO—C_6H_5$, all other things being equal, is 847·7.—The state of vegetation on March 21 and April 21, 1890, in Gembloux, Huccorgne, Liége, and Spa, by Prof. G. Dewalque. The observations that have been obtained of herbaceous plants are very discordant. It is estimated, however, that vegetation was from 6 to 8 days behind on March 21, and 4 or 5 days behind on April 21.—On the characteristic points of some remarkable lines in conics, by C. Servais.—On the curvature in curves of the second degree, by the same author.—Note on the development in series of sine, cosine, and exponential functions, by Prof. Alphonse Demoulin.

THURSDAY, JULY 17, 1890.

THE INDIAN CIVIL SERVICE AND THE INDIAN FOREST SERVICE COMPETITIONS.

THOSE who devote attention to educational questions are looking with interest for the publication of the new schedule for the Indian Civil Service competitions. But past experience of the Civil Service Commissioners, who are largely responsible for these matters, and on whom the various departments must chiefly rely for the carrying out of their ideas, causes the interest of many of us to be not unmixed with a considerable degree of anxiety lest there should be in this case a repetition of the recent Woolwich and Sandhurst *fiascos*. Therefore, notwithstanding the favourable character of Sir John Gorst's recent reply to Sir Henry Roscoe, we hope that those at the Universities who are interested in the question, and the leaders in science, will not yet rest upon their oars, but that they will bring under the direct notice of the authorities at the India Office the present position of science studies at the Universities and the views that are held there on this important subject, in order that the latter, who we believe hold fair views upon the subject, may be in a position to judge of the fitness of any scheme that may be submitted to them and of its correspondence or the reverse with the present condition of higher education. We bring this subject again under the notice of our readers, partly because of its importance, and partly because in the new regulations for the India Forest Service we have recently been afforded a fresh example of the inability of those who are officially intrusted with these matters to properly estimate the requirements of the public services. These new regulations are, no doubt, better than those which they are intended to replace in several respects, notably so in that the absurd list of fourteen compulsory subjects by which this examination has hitherto been distinguished has now been abolished, and also in that the examinations will now run somewhat closely on the lines of the army competition—a change which will probably secure for them a wider field of candidates than they have hitherto had. But, considered as a method of selecting those who are most likely to do good work in a scientific profession, the scheme must be pronounced to be a failure, since it will neither insure the selection of the most promising men for the particular service required of them, nor, as many will think, encourage those who intend to compete to give themselves a really liberal education.

The subjects and their mark values are as set out below:

Class I.—Obligatory Subjects.		
1. Mathematics, Elementary ...	2500	Not less than one-third of full marks in each of these subjects must be obtained to qualify.
2. English Composition	1000	
3. German	2000	
Class II.—Optional Subjects.		
4. Mathematics, Higher	2000	Any two, but not more than two, of these subjects may be selected.
5. French	2000	
6. Latin	2000	
7. Greek	2000	
8. English History	2000	
9. Botany	2000	
10. Chemistry	2000	
11. Physics	2000	
12. Physical Geography and Geology	2000	
Class III.—Additional Subjects.		
13. Freehand Drawing ...	500	Either or both of these may be taken up in addition to those in Classes I. and II.
14. Geometrical Drawing	300	

A close inspection of the scheme reveals at once certain serious objections to it. In the first place, whilst admitting that the authorities have done well to provide fairer opportunities for students whose education has been largely in literature, we must claim, both in the interests of the service and of the candidates, that those who seek admission as probationers for so essentially scientific a service ought in every case to be required to show some moderate degree of capacity for scientific work before they are admitted to their professional studies. The Professors at Cooper's Hill are men of the highest standing, and they will undoubtedly give an excellent training to all who are fitted to undergo it. But they cannot create scientific aptitude in those who are intrusted to them. Hence, if men who are deficient in the proper qualities are selected as probationers, either the service or the probationers must suffer; for it must happen, either that the scientific standard of some of those who are finally selected will be unduly low, or else that some probationers who ought never to have been selected will be finally rejected after much loss of time and much expenditure in money. To show how real this objection to the scheme is, it is only necessary to point out that under the new scheme a candidate may offer himself for examination in the following subjects with every reason to hope for success:—Elementary mathematics, English composition, German, Latin, Greek, drawing. We do not think that the staunchest upholders of the study of literature will support this selection of subjects as one by means of which a satisfactory judgment of the fitness of the candidates for a scientific profession can be made. It is plain that a young man who shows ability in these subjects may or may not have a reasonable degree of scientific aptitude also.

On the other hand, many will think that the new scheme permits even too great a neglect of literary studies on the part of those candidates whose bent is for science, since several combinations such as the following would also be possible:—Elementary mathematics, English composition, German, chemistry, physics. We are sure that many advocates of science teaching will feel that in this group of subjects literature is too much neglected; and we believe that a youth of nineteen or thereabouts might add to it another modern language, or some knowledge of Latin, with advantage to his studies in mathematics and science, as well as to his general education.

In connection with this question, too, it must be remembered that candidates are practically compelled by the severity of these competitions to stick to those subjects in which they are most likely to compete successfully, for a long period, often for several years, beforehand. So that, for example, a young man who is only moderately good at science and rather better at languages will be most likely to win a place in this scientific service by neglecting all scientific reading up to the age of nineteen or twenty years! Surely this is an example of how not to do it

It seems to us, therefore, that the proposed scheme for the India Forests Department imperatively requires

such amendment as shall secure evidence of a reasonable degree of capacity for science on the part of every probationer, whilst it would be well also if it could be made to encourage a rather wider range of literary study in the earlier education of those whose main interests lie in the direction of science. What is desirable could be attained in several ways. But it could, perhaps, be best effected by permitting candidates to offer themselves for examination in three subjects instead of two from Class II.; with the limiting condition that one at least of these three must be taken from numbers 5, 6, 7, 8, and one of them from 9, 10, 11, 12.

We trust that this subject may also be brought under the notice of the authorities at the India Office. It seems evident from the changes already made that they are in no way prejudiced against either scientific or literary studies, and we feel sure that if they will institute inquiries they will find that similar opinions to those we have expressed are widely held on this subject.

THE VOLCANOES OF HAWAII.

Characteristics of Volcanoes, with Contributions of Facts and Principles from the Hawaiian Islands: including a Historical Review of Hawaiian Volcanic Action for the past Sixty-seven Years, a Discussion of the Relations of Volcanic Islands to Deep-sea Topography, and a Chapter on Volcanic-Island Denudation. By James D. Dana. Illustrated by Maps of the Islands; a Bathymetric Map of the Atlantic and Pacific Oceans; and Views of Cones, Craters, a Lava-Cascade, a Lava-Fountain, &c. (London: Sampson Low, Marston, Searle, and Rivington, 1890.)

THE veteran geologist of the United States has rendered an inestimable service to science by the publication of this splendid monograph, which has just made its appearance simultaneously in this country and in the United States. To find any work on a similar subject comparable with it either in importance, or in the influence it is likely to exert upon geological thought, we must go back to the publication of Fouqué's "Santorin," of Von Waltershausen's "Etna," or Scrope's "Volcanoes of Central France."

The Hawaiian volcanoes are unquestionably the grandest on the face of the globe. Their vast dome-shaped masses, with slopes averaging from 6° to 8°, rise to heights of only 14,000 feet above the sea-level; but deep-sea soundings have shown that they stand on a floor 12,000 to 18,000 feet below that level, so that, as Prof. Dana points out, the higher volcanic mountains of the Sandwich Islands must have an elevation of not far from 31,000 feet above their bases! Beside these lofty and bulky domes, the graceful volcanic cones of the North and South American continents, of Japan and Java, sink into insignificance. The Hawaiian Archipelago contains no less than fifteen volcanoes of the first class, all but three of which appear to be now extinct. The active volcanoes of Hawaii give rise to lava-floods, which, in their bulk and in the distances they flow from their point of emission, are only surpassed by those of Iceland. In their remarkably non-explosive action, in the characters of their great pit-craters, in the wonderful liquidity of their lavas—giving rise to veritable fountains of molten rock—and in the beauty and singularity of some of their igneous products, the Hawaiian volcanoes are without a parallel anywhere else in the world.

The Hawaiian volcanoes appear to form two nearly parallel bands, which doubtless indicate great lines of fissure in the earth's crust, the extreme length of these being about 400 miles. The recent topographical surveys of the islands made by Prof. W. D. Alexander, Surveyor-General to the Hawaiian Government, and a number of recent soundings in the adjoining seas, enable us to realize, in a way that was not previously possible, the dimensions and forms of these vast volcanic piles.

Prof. J. D. Dana has enjoyed exceptional facilities for studying these unique centres of igneous activity. As naturalist of the U.S. Exploring Expedition, he visited the islands in November 1840, after the great eruption of Kilauea that had taken place in May of the same year. The work of the actual survey and description of the craters was unfortunately not committed to Prof. Dana; for the energetic, though scientifically untrained, head of the Expedition, Captain Wilkes, determined to undertake this task himself; and the naturalist was sent away to another station while the survey was in progress. Had Prof. Dana been present to advise and assist the surveying officers, it is clear that many unfortunate errors would have been avoided, and that the accounts of the volcanoes contained in the "Narrative of the United States Exploring Expedition" would have had far greater scientific value.

After his return to the States and his settlement at Yale College, Prof. Dana showed his continued interest in the Hawaiian volcanoes, by keeping up a constant correspondence with missionaries and other residents in the islands; and every great eruption was carefully chronicled in the pages of the *American Journal of Science*, which he has so long edited. The memoirs of Brigham and Captain Dutton, and the enlargement and correction of our topographical knowledge of the islands, resulting from the Government survey, seem once more to have aroused the author to a sense of the importance of the subject, and in 1887 he commenced a series of papers on the history of the changes in the Mount Loa craters. He had not proceeded far with this work, however, before he felt the need of a second personal examination of the district. With characteristic energy, he undertook, in spite of his advancing years, a ten-weeks' journey, involving over ten thousand miles of travel, in which he visited all the chief points of interest; and the book before us is the outcome and monument of his labours.

The work of criticizing and reconciling the accounts given by numerous travellers, beginning with notices written as long ago as the year 1823, has been admirably performed by Prof. Dana. Without his personal knowledge of the localities, and the aid afforded by the new and accurate maps of the islands, the task would, indeed, have been a hopeless one; for many of the descriptions were penned by unscientific and careless writers, and inaccuracies and exaggerations are encountered at every step. By sifting and correlating this confusing mass of evidence, however, the author is able to give a clear and connected narrative of the changes in the Kilauea crater, and to illustrate the position of its floor after each of the great eruptions, which took place in 1823, 1832, 1840, 1868, and 1886. The result is that we are furnished for the

first time with the means of judging of the real nature of the processes going on in the pit-craters of non-explosive volcanoes. A similar discussion of the records concerning Mokuaweoweo, the summit-crater of Mount Loa, enables the author to furnish an interesting, but necessarily less complete, narrative of the operations going on there during the same period. The want of anything like synchronous action between these two great craters in the same mountain-mass, *one of which is at an elevation of* 10,000 *feet above the other*, has often been remarked upon; and the truth of the conclusion—one which must always be taken account of in attempts to explain volcanic phenomena—is fully established in the work before us.

Prof. Dana forcibly illustrates the remarkable contrast between the effusive eruptions of the Hawaiian volcanoes with their extremely liquid and perfectly fused basaltic lavas, and the explosive outbursts of Vesuvius, Krakatão, and Tarawera. He describes the characters and limited distribution of the curious glassy lavas, and their derivatives—the curious Pele's hair and the beautiful "thread-lace scoriæ"; and he points out the inaccuracy of the early chemical analyses of the Hawaiian lavas, which have misled so many subsequent writers. His remarks on the characteristics and origin of the chief varieties of the lava, and especially of the pseudo-bombs—vast pillow-like masses of lava covered with a thin vitreous crust—are remarkably interesting and suggestive.

One of the most valuable chapters in the book is that on the petrographical characters of the Hawaiian lavas, supplied by the author's son, Prof. E. S. Dana. The singular fissile basalts of the higher cone, which resemble phonolite, and several other remarkable types are here described for the first time. Very noteworthy are the curious feathery forms of augite which occur in some lavas, and the strangely-elongated crystals of olivine which are found in others. But the part of the chapter which will unquestionably awaken the greatest amount of interest in the minds both of mineralogists and geologists is that which deals with the curious stalactites found in certain caverns in the lavas. That these stalactites are formed by aqueous action there cannot, as Prof. E. S. Dana shows, be any reasonable doubt. Yet the stalactites are built up of crystals of felspar, augite, and magnetite, all the constituents formed by igneous action in the lavas themselves, being present, with the exception of olivine! All students of mineral synthesis are acquainted with the fact that the same species can often be formed by several, and sometimes by very diverse, methods. Mr. Sorby has even shown how fragments of quartz-crystals, originally formed in a granite or other igneous rock, may after enormous intervals renew their growth and become complete crystals again under purely aqueous conditions; so that the same crystal may in different parts be the result of totally different kinds of action. In spite of these facts, however, few petrographers would be prepared to find that, from aqueous solutions, rocks made up of felspar, augite, and magnetite could be formed in the way described in this interesting essay. Prof. E. S. Dana not unnaturally announces these remarkable conclusions with some diffidence and reserve; yet it is impossible to find any flaw whatever in the line of argument by which he seeks to establish their truth.

Prof. J. D. Dana has prefaced his description of the Hawaiian Islands by a sketch to which the title of "Characteristics of Volcanoes" is more directly applicable. In this introduction, which only extends to some 27 pages, many of the great problems of vulcanology are discussed with singular clearness and freedom from bias.

The work concludes with two interesting appendices, the first on "Volcanoes and Deep-sea Topography," and the second on "Denudation of Volcanic Islands; its Amount a Mark of Age." The book is well illustrated with maps and sketches, and some plates reproducing photographs will serve to give a just idea of the peculiar lava cascades and fountains of Hawaii—phenomena which have not unnaturally excited the imagination of untrained observers, and given rise to startling drawings and florid descriptions in popular works of travel. But the sober truth is, that the wonders of Hawaii stand in no need either of exaggeration or embellishment from the writer or the artist.

We heartily welcome the volume as the crowning labour of the greatest of America's men of science—the latest, and not by any means the least important, of a long series of contributions to science on very diverse subjects, but of unvarying excellence. J. W. J.

A POLYGLOT MEDICAL VOCABULARY.

Terminologia Medica Polyglotta: a Concise International Dictionary of Medical Terms. Compiled by Theodore Maxwell, M.D. Cantab. (London: Churchill, 1890.)

THE current literature of medical subjects is extensive and polyglot, and those who endeavour to keep themselves abreast of the most recent research in any branch require to dip into works in many languages, and need to have at hand some such aid as the present vocabulary, wherein they can seek for the several vernacular synonyms of those newer technicalities which modern developments of science have produced, and which are not to be found in the ordinary dictionaries. Moreover, it is often necessary that the special senses in which some of the older and more general words are used by medical writers should be defined. One may be very well acquainted with the anatomy of the brain as described in the English standard works, and yet have much difficulty in following the descriptions in German or French books on cerebral pathology, when vernacular names are used for the several parts; and one longs for some international agreement as to a uniform system of scientific terminology like the Latin generic and specific names of the Linnæan nomenclature.

The compilation of a new dictionary is a task involving an enormous amount of labour, and when, as in the work under notice, the synonyms of each term in seven languages have to be sought and tabulated, the difficulties of the undertaking are seriously increased. The compiler has evidently expended great care, and exercised much judgment in his toilsome task, and doubtless this vocabulary will prove of much help and be highly appreciated by students of foreign medical literature. The typography is excellent and clear, and the work is singularly free from errors of the press.

It is questionable whether the selection of French as the fundamental language was a wise choice. There are

fewer original terms in the French scientific vocabulary than in either English or German; fewer modern writings of value in the medical literature of France than in either of the other great European literatures; and fewer students of medical literature in French-speaking countries than in either English or German-speaking countries. The Russian element might also without very much loss be eliminated; for as there are no Russian-French references it can be of little assistance to anyone reading Russian literature, and will only be of value to the limited class of Russian students of other literatures, or the still more limited class of foreigners writing medical works in Russian.

The special function of a work like the present is to supplement, not to supplant, the ordinary dictionary; therefore such a work should be reduced to as small a bulk as possible. To this end there should be as little overlap as possible, as there is no advantage in including such words as are to be found in the ordinary dictionaries, unless there is something specific in their use to be explained. In the work before us, this principle has not been adopted, and its size has consequently been unduly enlarged by the introduction of many common words which have no such peculiarities. Thus, taking at random the pages 184-5, there are the words Heirath, Heavy, Heat, Heating, Hebung, Hebel, Heften, Heifer, Height, Heiss, Heizung, Helfen, Hell, Helm, Hembra, Hemd, Heaviness, Heiter, Helios. In these pages alone, one-fourth of the entries are common dictionary-words. (By inadvertence, Helios, the sun, is said to be Latin.) Turning at random to another page (445) there are seventeen words in a row—Wave, Wax, Weak, Weaken, &c.—of the same description. One might, perhaps, defend the introduction of the word "Stays" in the sense of corset, but one does not see why "Star" (étoile) or "Stamp" (timbre) should have space devoted to them.

By rigid adherence to a definite order of languages in the enumeration of synonyms, the bulk of the work has also been largely increased. Much space would have been saved, and the utility of the book by no means impaired, if, when the same word was used for the same idea in two languages, instead of the repetition of the word the initials indicating the languages had been prefixed to one entry of the word. Thus, instead of wasting three lines with "E. Opodeldoc, soap-liniment; G. Opodeldoc; I. Opodeldoc," or two lines with "I. Organo; S. Organo," E. G. and I. might have been prefixed to the one, and I. and S. to the other. There is no gain of clearness in the tabulation, and a distinct loss of handiness; for it is especially true in the case of a dictionary that the greater the book the greater the evil.

While in most cases the author has confined himself to the enumeration of synonyms, there are some words to which he has appended definitions. The principle upon which words have been selected for this distinction does not seem apparent; for instance, it was surely unnecessary to define "Faux (f. fausse), adj., qui n'est pas vrai." Some of the definitions are curious; thus, "delusion" is defined as "a belief in something incredible to sane people, resulting from diseased working of the brain convolutions." It is doubtless right that "Daft" should appear in a polyglot dictionary, but it can scarcely be reckoned as English, and is as much deserving of having its nationality indicated as "Knocked up," which is given as "(en Amérique) enceinte."

In a few cases inconsistencies of spelling have eluded the corrector's eye: thus, the adjective "Lacrymalis" is accurately given, but a few lines below the neuter form appears as "Os lachrymale"; Aneurysm is spelled with an *i*; but oversights of this kind are very few.

The author has adopted in some cases the useful plan of marking with an asterisk those words under which the full synonymy is given. In a few instances this has become misplaced; thus for the Latin "Caduca" the equivalent "membrana decidua*" is given, but there is no such entry under "membrana," and opposite "Decidua" there is simply the French synonym "caduque," which is the heading to which the star should have been appended.

There are some words which one would have expected to have place in such a work that are not to be found. Ache, Aching, Acromegaly, Caul, Limbus, Limbic, Lobe, Monoplegia, Laparotomy, are a few of these. Black alder is given, but neither black wash nor black draught. Red precipitate, Citrine ointment, Daffy's elixir, are surely as deserving of place as Dover's or James's or Gregory's powder.

Fault-finding is at all times an ungrateful task, but it becomes especially unpleasant when the subject is a work of real merit, and we have indicated these weaknesses so that in subsequent editions the usefulness of the work may be increased. If its size were diminished by the exclusion of ordinary dictionary-words, by the better grouping of those that are identical, and by the judicious excision of unnecessary definitions, a portable, useful work would be produced, which we doubt not would find its place on the desk of the majority of students of foreign medical literature.

ALEX. MACALISTER.

MASKS FROM NEW GUINEA AND THE BISMARCK ARCHIPELAGO.

Masken von Neu Guinea und dem Bismarck Archipel. By A. B. Meyer. *Königliches Ethnographisches Museum zu Dresden.* Band VII. Folio, pp. 15, Plates 15. (Dresden: Stengel and Markert, 1889.)

DR. A. B. MEYER has written the seventh of the series of fine publications of the Royal Ethnographical Museum of Dresden which are brought out under his direction. He has selected for description and illustration the masks from New Guinea and the Bismarck Archipelago which are to be found in the collection under his care. The descriptions are as a rule very brief, but they are to the point, and indicate the zoological training of the author. The latter is shown not only by the precision of the descriptions, but also by the addition of the generic name to the animals represented by the masks or used in their adornment. Of the 83 specimens in the Dresden Museum, 61 have been illustrated in this memoir in a most admirable manner by a photographic process the excellence of which leaves little to be desired. On comparing these photographs with woodcuts of similar objects the advantage of the former is at once apparent, as the texture of the various substances used in the manufacture of the masks is faithfully rendered, and

the faultiness of the original design or pattern is not glossed over by an engraver. It is a great pity that the magnificent collections in the British Museum cannot be rendered available for home study by the publication of similar photographs.

It is to be regretted that Dr. Meyer confined his account of the masks to those contained in the Dresden Museum, and has not compared these with the specimens which are to be found in other museums.

A good opportunity for a thorough treatment of the subject has thus been lost. For example, allusion is made to the occurrence of masks in the Elema district of the Papuan Gulf, but no description or figure is given of them, although numerous specimens of these have found their way into museums. Of the eight masks which are figured from Torres Straits, one of the most characteristic varieties is unrepresented—that one which represents a crocodile's head surmounted by a human face. A fret pattern occurs on a mask from Jervis Island. This is alluded to by Dr. Meyer, and is compared with somewhat similar patterns, of which woodcuts are given, on two masks from German New Guinea, and with two patterns on arrows from Dutch New Guinea. The Torres Straits pattern, unlike the others, is precisely similar to the common form of the pattern, and as it does not occur on other objects from that district we can only conclude, contrary to Dr. Meyer, that it was directly copied from some introduced object; the same mask is further ornamented with some imported red woven material. Dr. Meyer suggests that the helmet masks from New Ireland, and the feather helmets and masks from the Sandwich Islands, are reminiscences of the helmets of the Spanish voyagers of the sixteenth or seventeenth century. He also considers it probable that the use of masks in this part of the world originated in New Ireland, and extended through New Hebrides to the northern portion of the German territory of New Guinea, and thence by an overland route to the head of the Papuan Gulf and Torres Straits. Other routes were northward to the Caroline Island, Mortlock, and south-east to New Caledonia. Dr. Meyer has been able to discover very little concerning the uses of masks; all that he can say is that they are used in "masquerades, festivals, general feasts, secular, religious, and war dances." It is, however, very probable that particular kinds of masks are used for definite occasions, and that the masks which are worn say during initiation ceremonies could not be put on at a seasonal festival. There is no evidence, so far as British New Guinea is concerned, that masks are ever worn at the festive or secular dance, or at the war dance; they appear to have a definite sacred or religious significance.

This valuable memoir concludes with an interesting quotation from Weisser's paper on masks from New Ireland. Early in May the men of one village repair to another village with which they have a feud. Each man then puts on the mask which he has been secretly preparing during the previous year, and the men of the one village dance opposite to those from the other. After this they have a feast, and exchange sago cakes, which they eat with caution, fearing poison; criticism of the masks of the opposite faction affords ample opportunity for the continuance of the animosity.

A. C. H.

OUR BOOK SHELF.

Larva Collecting and Breeding. By the Rev. J. Seymour St. John, B.A. (London: William Wesley and Son, 1890.)

THE alternative title of this little volume, which is of convenient size for the pocket, is "a hand-book to the larvæ of the British Macro-Lepidoptera and their food plants; both in nature and in confinement, with authorities," and is sufficiently explanatory of its scope and objects. The arrangement of the first portion of the book is entomological, of the second and concluding portion botanical. In the former the larvæ are arranged and named according to "The Entomologist Synonymic List of British Lepidoptera," and the food plants are enumerated as subsidiary to these. In the second half the food plants are specified in the order of the "London Catalogue of British Plants" (eighth edition). The book is therefore susceptible of a twofold use; it will induce the entomologist to become a field botanist, and conversely it will greatly aid the student who has some knowledge of the native flora in his efforts to become practically acquainted with the lepidopterous larvæ. So much energy is misdirected, particularly by young people, in making collections of butterflies and moths for the mere sake of collecting, that the intelligent use of this little book is calculated to effect a salutary change. It will, at least, direct greater attention to the life-histories of the Lepidoptera, and if it should be instrumental in inducing the collector to preserve and mount the larva alongside the male and female specimens of the mature butterfly or moth, so much the better. It is too common a practice to ignore the "grub" as unlovely and despicable; though from an economic point of view it possesses a higher interest than the winged insect, and is certainly not inferior to it in importance from a scientific standpoint. Nearly all the Lepidoptera which are familiar in this country as crop-pests are actively injurious only in the larval stage.

As the author intimates, such a work as this is necessarily a compilation, and, from its very nature, it is hardly possible to make it exhaustive. All who use it in the field will find opportunities to annotate and amplify it, and possibly to suggest emendations. The common names as well as the systematic names of the plants are given, and it might be useful if in a future edition the common names of the insects were, as far as possible, also enumerated. A few misprints have escaped notice, as *Galium sexatile* (p. 103), and *Rynchospora alba* (p. 137).

Mr. St. John's book represents a good idea well carried out, and it should have the effect of stimulating the study of natural history in the field.

Practical Chemistry for Medical Students. By Samuel Rideal, D.Sc. (Lond.), F.I.C., F.C.S., F.G.S. (London: H. K. Lewis, 1890.)

THIS book is intended by the author to embody the tests for those substances which a medical student is required to identify at the first examination of the Conjoint Examining Board in England. The attempt to compress this information into 53 small pages has resulted, as might have been expected under the circumstances, in a cram-book. Indeed, the only justification, if such it can be called, for the addition of another to the many works on qualitative analysis is that the book contains in the minimum space the knowledge required for a special examination. This knowledge is, however, frequently of a questionable nature. Thus, "calcium sulphate, $CaSO_4$ (*gypsum*)," is described as a "white *amorphous powder*;" "sodium carbonate, Na_2CO_3," as a "white solid, crystalline *or* amorphous;" "ferric chloride, Fe_2Cl_6, a yellow amorphous *powder*," and so forth: statements of a kind which, although they constitute a large portion of the book, are both fragmentary and inaccurate. The endeavour to

attach valency values to the metals is carried out in all cases with the exception of iron, to which no value is affixed. The reason for this omission is not obvious, as the author does not hesitate to call lead a dyad, antimony a triad, &c. Amongst minor points the use of potassium antimony tartrate for potassium antimonyl tartrate, of arsenic acid for arsenic pentoxide, may be noticed.

The book may go some way to fulfil the author's expectation that it will give the student "some acquaintance with the art of test-tubing," but that it will materially increase his knowledge of the principles of practical chemistry, or sharpen his appreciation of the *raison d'être* of a chemical process, is another matter.

Manual of Pharmaceutical Testing. By Barnard S. Proctor, F.I.C. Pp. vii., 176. (London: *The Chemist and Druggist*, 1890.)

THIS book is a collection of tests suitable for ascertaining the purity of the chemicals of the British Pharmacopœia, &c. The tests described are the simplest possible, and can be carried out with the apparatus and chemicals in use at the dispensing counter. They apply more especially to the impurities of manufacture than to adulterations. In many cases they are simply those recommended by the British Pharmacopœia for determining if the purity of a material falls short of the required standard. As a rule they are qualitative, and sufficiently accurate for the purpose in view, although quantitative methods, more especially in determinations of solubility, or fixed residues of volatile liquids, are employed. The book contains a chapter on manipulation, which includes the method of weighing precipitates, and an index, and will be found a handy volume to the pharmacist.

The Encyclopædia of Photography. By Walter E. Woodbury. (London: Iliffe and Son, 1890.)

THIS work, which will be concluded in about twelve parts, is written on the same lines as other photographic encyclopædias, but treats especially of the sciences of optics and chemistry. The art of photography being so largely practised nowadays, it is curious what a small percentage of those who have taken it up know anything about optics or chemistry, which form the basis of the whole subject.

Throughout the book the author has borne this well in mind, and has spared no pains to place before the reader, in a simple and clear manner, the principles underlying the formation of images, the construction of lenses, chromatic and spherical aberration, the theory of atoms and molecules, and many other very important points relating to optics and chemistry.

The illustrations, which will be about 200 in number, consisting of explanatory sketches and diagrams, will be found, if up to the standard maintained in this first part, to serve their purpose well.

For amateurs this encyclopædia should be very useful, as it is written especially for beginners, and some of the most complicated terms likely to lead to confusion are avoided as much as possible.

Dynamics for Beginners. By the Rev. J. B. Lock, M.A. Third Edition, stereotyped. (London: Macmillan and Co., 1890.)

THE author has fully succeeded in supplying the want that has been long felt, of a book which should explain the elementary principles of dynamics, illustrating them by easy examples in a manner suitable for use in schools with boys of ordinary mathematical attainments.

Section I. deals with rectilinear dynamics, in which the fundamental principles are explained. The words "velo" and "celo," abbreviations for unit velocity and unit acceleration respectively, are here used, and the author says in the preface, "Of their value for the purposes of teaching and explanation I have received the very strongest testimony from those best qualified to judge."

Sections II. and III. treat of "Direction" and "Illustrations," the former dealing with the parallelograms of distances, velocities, and accelerations, chords of quickest descent, &c., the latter with projectiles, oblique impact, relative motion, hodograph, &c.

Work, energy, power, are discussed in Section IV., and there is a chapter on the indestructibility of matter.

An excellent set of examples is collected at the end, and a series of examination papers is added, taken from the various examinations held from time to time at Oxford and Cambridge.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"The Climates of Past Ages."

I FEEL somewhat disappointed not to see a flood of correspondence in your pages arising out of Dr. Neumayr's very interesting lecture on the climates of past ages. The subject is difficult and complex, and the factors of the problem are no doubt various and of different kinds. I wish to make a few remarks on some of these.

It seems impossible to doubt that the sun is losing heat; and, consequently, that the quantity of heat annually received by the earth from the sun is less than it once was. Now, one of the most remarkable of the facts before us is the evidence, from fossil vegetation, of comparatively warm climates in the polar regions. There is no similar evidence respecting the equatorial regions; but it is probably impossible that such evidence should be preserved, so that its absence proves nothing as to the equatorial climate of the same period; but it is worth noticing that, if we suppose the force of solar radiation increased, the increase of terrestrial temperatures will be greater in high than in low latitudes, because, with the increased quantity of heat received into the atmosphere, an increased quantity will become latent by evaporation in the lower latitudes, and will be carried to the higher latitudes by vapour-bearing winds.

If our planet had neither atmosphere nor ocean, the temperature of the higher latitudes could be raised only as a direct result of increased solar radiation. If it had an atmosphere but no ocean, the increase of the temperature of the higher latitudes would be assisted by heat-bearing winds; and this would be at the expense of the temperature of the lower latitudes, which would be lowered by the heat so carried away. In the actual case of our earth, with both atmosphere and ocean, this action will be greatly increased by the power of vapour-bearing winds to carry heat in the latent form, which again becomes sensible heat on the condensation of the vapour. This appears to show that a considerable increase of temperature might be produced in the higher latitudes by a comparatively small increase in the force of solar radiation.

Dr. Neumayr says that the cause of the glacial climate is quite unknown; and at the same time he asserts that both hemispheres—the northern and the southern—were glaciated at the same time. I dispute both of these opinions. I think Mr. Croll has shown the direction in which the explanation of the glacial climate is to be sought; and if this is so, the two hemispheres were not glaciated at the same time, but alternately.

If, during a glacial period, the northern and the southern hemispheres were each alternately glaciated for geologically short periods, this would account for the fact mentioned by Dr. Neumayr, that the glacial period appears not to have been continuous, but interrupted by periods of milder climate. Croll's theory accounts for this. His theory is, that glacial periods occur at those astronomical epochs when the eccentricity of the earth's orbit is at its greatest; and a glacial climate is produced in the two hemispheres alternately, according as the

summer of each hemisphere is in perihelion or in aphelion. This, in consequence of the precession of the equinoxes, will occur at intervals of about 25,000 years. That is to say, if in either hemisphere the summer is now in perihelion, at the end of 12,500 years its summer will be in aphelion, and in 12,500 years more it will be in perihelion again. Mr. Croll maintains that glaciation occurs in the hemisphere where there is perihelion summer and aphelion winter, because of the intense cold of such a winter. I think, on the contrary, that the facts of climate which come under our observation show that winter cold has little or no effect in producing glaciation; and that a cold summer, which leaves the winter snow unmelted, is the most favourable condition for glaciation. Such is the climate of the Antarctic continent now. It is obvious that a summer in aphelion, when the eccentricity of the earth's orbit was many times greater than now, must have been a very cold summer.

This theory of the glacial climate appears perfectly satisfactory. The astronomical cause is known to exist, the geological effects are known to exist, and the effect is that which the cause must necessarily produce.

Even if it were true that a glacial climate prevailed in both hemispheres at the same time, no geological evidence could prove such a fact. No geological evidence could tell whether glacial mounds in Norway and in Patagonia, for instance, were strictly contemporary, or separated in date by an interval of 12,000 years.

Dr. Neumayr appears to retain the old notion that changes of climate may be to some extent due to changes in the position of the earth's poles. I am no mathematician, and cannot speak on such a subject with any authority, but Sir William Thomson believes he has proved that the earth is for all dynamical purposes perfectly solid and rigid; and I should think that the axis of rotation of a perfectly rigid oblate spheroid is unchangeable.

Belfast, July 10. JOSEPH JOHN MURPHY.

The American Meteor.

I RECEIVED the following observations from my son, G. S. Henslow, who witnessed the fall of the meteor referred to lately in NATURE. I forward it, as it may perhaps interest some of the readers of this journal.

"The meteor fell about 5 p.m., and divided in mid-air, part of it falling in Minnesota near a town called Kasota; this portion was not found. The other and larger piece fell near Butt City, Iowa. The two places are about a hundred miles distant. It exploded on reaching the ground into myriads of fragments, a number of which have been picked up and sold at fabulous prices. The State University of Minnesota bought the largest piece. It fell on the open prairie, but broke into such small fragments that the surrounding soil was scarcely disturbed at all. We all saw it fall here at Windom. It illuminated the southern sky, and left a cloud resembling the smoke from the funnel of an engine. On bursting, there was a sound like a sharp peal of thunder." G. HENSLOW.

SPONTANEOUS IGNITION AND EXPLOSIONS IN COAL BUNKERS.

AT the Royal United Service Institution, on Friday, July 4, a paper on this subject was read by Prof. Vivian B. Lewes, Royal Naval College. Rear-Admiral N. Bowden-Smith was in the chair.

The lecturer, after premising that in the fast ocean steamers it is now becoming an event of frequent occurrence for the contents of the bunkers to spontaneously ignite, whilst in the Service such a thing as fire in the bunkers is practically unknown, and an occasional, although fortunately very rare, explosion of gas is the worst trouble which the coal stores of our naval monsters have given rise to, directed attention to the causes which give rise to the so-called "spontaneous ignition of coals," and traced the particular circumstances which tend to increase the tendency to it.

The pyrites or coal brasses present in the coal when exposed to dry air undergo little or no change, but when moisture as well as air is present they absorb oxygen and combine with it, forming sulphates of iron, and the ordinary explanation of the spontaneous ignition of coal is that this process of oxidation causes a rise of temperature in the coal which determines its ignition; this, however, has of late years been much doubted, and it can now be proved that the pyrites when present in ordinary quantities are perfectly incapable of doing more than adding slightly to the general rise of temperature, although when present in very large masses they may increase the tendency of the coal to spontaneous combustion by swelling during oxidation, and causing the coal to crumble, and also by setting free sulphur, which, having a lower melting-point of ignition than coal (482° F., or 250° C.) would lower the temperature at which the mass would catch fire.

The real causes which give rise to heating and ignition in any large accumulation of coal are twofold. First, the absorption of oxygen from the air by the carbon; and secondly, the chemical action set up by the absorbed oxygen with the hydrocarbons of the coal.

The most important point to be noticed is the extraordinary effect which initial temperature has on the rapidity of chemical actions of this kind. At a low temperature, and indeed up to about 100° F. = 38° C., the absorption of oxygen, and consequent chemical action, will go on slowly with practically little or no chance of undue heating taking place, but directly the temperature exceeds 100° F., then, with some classes of coal, ignition is only a question of time and mass.

Although the ignition point of various coals lies above 700° F., yet if many of these coals are powdered, and are placed in perforated zinc cases in masses of 2 lbs. or upwards, and these are kept at a steady temperature of about 250° F. in an oven, ignition will generally follow in a few hours; whilst between this and 150° F. it will take days instead of hours for the same result to follow, and at ordinary English temperatures several thousand tons of coal would have to be stored in a very broken condition before any risk of heating or ignition would ensue. In considering this question with regard to coal bunkers, it must be remembered that, although the considerations which had to be taken note of in the case of coal-laden ships still exist, yet they are considerably modified by the smallness of the amount of coal carried, and by the methods of loading and storage employed.

Liability to spontaneous ignition increases with:—

1. *The increase in the bulk of the cargoes.*—Evidence given before the Royal Commission of 1875 showed that in cargoes for shipments to places beyond Europe the cases reported amount to ½ per cent. in cargoes under 500 tons; in cargoes from 500 to 1000, 1 per cent.; 1000 to 1500, to 3·5 per cent.; 1500 to 2000, to 4·5 per cent.; and over 2000 tons, to no less than 9 per cent. Mass influences this action in two ways:—

(*a*) The larger the cargo, the more non-conducting material will there be between the spot at which heating is taking place and the cooling influence of the outer air.

(*b*) The larger the cargo the greater will be the breaking-down action of the impact of coal coming down the shoot upon the portions first loaded into the ship, and the larger thereby the fresh surface exposed to the action of the air.

2. *The ports to which shipments are made* (26,631 shipments to European ports in 1873, resulting in only ten casualties, whilst 4485 shipments to Asia, Africa, and America gave no less than sixty).—This startling result is due to the length of time the cargo is in the vessel, the absorption and oxidation being a comparatively long action, but a far more active cause is the increase of temperature in the tropics, which converts slow action into a rapid one.

3. *The kind of coal of which the cargo consists* (some coals being especially liable to spontaneous heating and ignition).—There is great diversity of opinion on this

point, but it is pretty generally admitted that cases of heating and ignition are more frequent in coals shipped from east coast ports than in South Wales shipments. So much, however, depends upon the quantity of small coal present, that a well-loaded cargo of any coal would be safer than a cargo of Welsh steam coal in which a quantity of dust had been produced during loading.

4. *The size of the coal* (small coal being much more liable to spontaneous ignition than large.)—This is due to the increase of active absorbent surface exposed to the air, a fact which is verified by the experience of large consumers of coal on land; gas managers recognizing the fact that coal which has been stamped down or shaken down during storage is more liable to heat than if it has been more tenderly handled, the extra breakage causing the extra risk.

5. *Shipping coal rich in pyrites (or brasses) whilst wet.*—The effect of external wetting on coal is to retard at first the absorption of oxygen, and so to check the action; but it also increases the rate of oxidation of the pyrites, and they, when oxidized, swell and split the coal into pieces, and this increases heating due to the exposure of fresh dry surfaces.

6. *Ventilation of the cargo.*—For ventilation to do any good, cool air would have to sweep continuously and freely through every part of the cargo—a condition impossible to attain in coal cargoes—whilst anything short of that only increases the danger—the ordinary methods of ventilation supplying just about the right amount of air to create the maximum amount of heating. The reason of this is clear. A steam coal absorbs about twice its own volume of oxygen, and takes about ten days to do it under favourable conditions, and it is this oxygen which, in the next phase of the action, enters into chemical combination, and causes the serious heating. Ventilation, such as used to be sometimes arranged for by a box shaft along the keelson with Venetian lattice up-shafts, supplies about as much air as is necessary to produce the results which end in spontaneous ignition.

7. *Rise in temperature in steam colliers, due to the introduction of triple-expansion engines and high-pressure boilers.*—The increase in stokehold temperature, due to this, is from 5° to 10° F., and this affects the temperature of the adjacent parts of the vessel.

In the coal bunker, the question of mass, which plays so important a part in a hold laden with coal, is almost entirely eliminated, as 50 to 400 tons would be about the capacity of any ordinary bunker, and the cases of spontaneous ignition in masses of coal less than 500 tons do not amount to more than ¼ per cent. The question of initial temperature, therefore, becomes the one important factor. Bunker fires are almost entirely confined to vessels in which the bunker bulkheads are only separated from the funnel by a narrow air-space, or are in close proximity to the boilers themselves; but where the bunkers are stepped back from the funnel casing and boilers, spontaneous ignition is a great rarity. If coal is kept at a high temperature, even though it be far below its igniting point, ignition is only a question of time, and if the bunker coal next the bulkhead is kept at 120° F., any coal with a tendency to absorb oxygen will run a great chance of igniting within a few days. In order to prevent spontaneous combustion of the coal under these circumstances, all that is necessary is to reduce the temperature of the bulkhead in contact with the coal, as if this is kept at a temperature not exceeding 80° to 90° F., there is little or no fear of the oxidation of the hydrocarbons of the coal proceeding with such rapidity as to cause ignition in such a quantity of coal as can be carried in the bunkers, the iron decks, by subdividing the mass, also helping to reduce any risk. In order to reduce the temperature to the required extent, it would be necessary to make the bulkheads close to any heating surface, such as the funnel casing, double, and the side spaces six inches apart, the inner wall being provided at intervals with water-tight openings, through which the interior space can be coated with protective compositions from time to time. Through this double casing sea-water would be allowed to circulate very slowly, and would effectually prevent any undue rise of temperature, whilst to make the arrangements complete a thermostat should be fixed on the inner plate of each bulkhead, which, if the temperature rose to 100° F., would ring a bell in the captain's room, when the rate of flow of water could be increased until the required fall in temperature took place. Should this arrangement prove impossible from any structural cause, then a rapid current of air forced through the bunkers by means of a fan, or even an up-current formed by a good air-pump ventilator in the crown of the bunker, would go far to keep the temperature within safe limits. If such an arrangement were adopted in the fast liners, bunker fires would become a thing of the past, whilst such an arrangement of double bulkhead and water circulation would also solve the still more important problem of how to keep the magazines on board Her Majesty's ships at a sufficiently low temperature to fit them for the storage of E.X.E. and S.B.C. prism powders, and the still more delicately constituted smokeless powders, none of which could otherwise be kept in the auxiliary magazines of the new programme ships; as for safety they are placed between the boilers, and must, of necessity, reach a temperature far above that which any powder could stand without losing moisture, and in consequence developing far higher strains than the guns should properly be subjected to.

The question of explosions in coal bunkers and in the holds of coal-laden ships is a subject totally distinct from that of spontaneous ignition. During the conversion of woody fibre derived from various forms of vegetation into coal, considerable quantities of a gaseous compound of carbon and hydrogen, called methane, marsh-gas, or light carburetted hydrogen, is evolved, and as the action has been spread over long ages most of this gas has found its way to the surface of the coal seam and has diffused itself through the superincumbent soil and has escaped; but a portion has been occluded (absorbed) in the pores of the coal itself, and some also imprisoned in small cavities and fissures in the coal. Marsh-gas, when pure, is perfectly non-explosive, and burns quietly with a faint luminous flame, producing, as the products of its combustion, carbon dioxide and water vapour, but when mixed with ten times its own volume of air, and a light applied, it explodes with a force equal to about 210 lbs. on the square inch. Another cause which tends to increase the danger of explosion is that if the air is charged with fine coal-dust, less than one per cent. of marsh-gas mixed with it gives an explosive mixture, and also extends the area of explosion. In both colliers and coal bunkers the risk of explosion is greatest during the first ten days after shipment.

Marsh-gas is a non-supporter of combustion, so that the presence of the gas, or a mixture of it with air, if present, is a safeguard against spontaneous ignition; and if the precautions pointed out to prevent ignition were carried out in conjunction with simple precautions against explosion, explosions and fires in coal cargoes and bunkers would soon be a thing of the past.

The lecturer strongly advocated the adoption in the bunkers of all new vessels of the double bulkhead, and water circulation to such portion of the bunkers as impinge upon any unduly heated portion of the hold, and that all bulkheads should be made gas-tight; whilst in bunkers containing not more than 300 to 400 tons of coal, as thorough ventilation as possible should be obtained by fitting water-tight air-pump ventilators in the deck above the surface of the coal, while inlets for as cool air as possible should be provided at the bottom of the bunkers, and, where necessary, air driven in from the

fan. Under no conditions should any but safety-lamps be used in coal holds or bunkers.

A discussion followed, and the proceedings closed with a vote of thanks to the lecturer.

A WINTER EXPEDITION TO THE SONNBLICK.[1]

IT is not often that an Alpinist finds leisure to spend a month in winter at an altitude of 10,154 feet above the level of the sea. It may, therefore, interest the members of the Alpine Club, to have the experiences of one who, though not a member of their Society, yet was fortunate enough to make the unusual ascent, which was chiefly undertaken in the interests of science.

It is well known that since 1886, thanks to the united efforts of the Alpine Club, and of the Imperial Austrian Meteorological Society, and in a special manner to the energy and public spirit of Herr Ignaz Rojacher, there is now a thoroughly equipped Observatory on the highest peak of the Sonnblick. This Observatory has been established with the view of affording to students of natural science, physics, astronomy, and meteorology, the means of making such observations as are only practicable at great heights; and of providing them with accommodation in a part of the building which has been named by the owner "The Study."

In carrying on certain inquiries which are only to be solved on high mountains, I had for this purpose spent a month in the summer of 1881 on the Hoch Obir (6716 feet) in Carinthia, and I determined the first winter after the erection of the Observatory on the Sonnblick still further to resume the investigations in a situation which afforded a clear, cold, winter atmosphere, which was absolutely necessary. I was unfortunately unable to realize my intention the first winter (1887), which was the more to be regretted inasmuch as the winter of 1887, and especially the month of February, was unusually fine, whereas that of 1888 was the severest ever known. The "oldest inhabitant" of those parts had no remembrance of such heavy falls of snow and such dark and stormy weather as we experienced in the February of 1888—the month for which I had made all my arrangements for an expedition to the Sonnblick.

My expedition was undertaken with the following objects:—(1) To investigate the radiation of the earth into space, and the irradiation of the atmosphere upon the earth's surface, in order to ascertain, more accurately than had hitherto been done, the temperature of the aërial envelope of the earth. (2) To investigate the question of the blueness of the sky. (3) To discover whether the sparkle of the stars was altogether due to the lower strata of air. Having had a grant from the Imperial Academy of Sciences in Vienna for the purpose, I succeeded in enlisting the services of Dr. Trabert, a young indefatigable man of science, as assistant, to make simultaneous observations on the Rauris, whilst I observed on the Sonnblick.

We reached Lend on the morning of February 3, where we handed over our seven cases of scientific instruments, and my provisions for a month's sojourn on the Sonnblick, to Herr Rojacher's men, who conveyed the whole on a couple of sledges through Embach to Rauris; we driving to Kitzloch Rauris, where we found Herr Rojacher awaiting us, and, after a tough climb of an hour and a quarter up the mountain pass of Kitzloch, we proceeded by sledge to Rauris.

This first day was perhaps the finest during our stay in the Rauris Mountains; on the next, it began to snow; and it was in a heavy snow-storm that I had to set out for Kolm; and so heavy was it, that it was with the greatest difficulty that Rojacher and I, in our sledge, followed by the *Rossknecht* with my baggage, were enabled to reach the Bodenhaus. From thence, through the woods, to Kreuzbichl, the snow fell thicker and thicker, and it seemed as if we should never get to our destination. Beyond Kreuzbichl there was no path of any sort, and we had simply to wade through the deep snow for fully an hour, before we reached Kolm, Herr Rojacher's residence (5249 feet). On my arrival, I was just in time to telephone to Rauris that I had reached so far in safety, the telephone communication being immediately thereafter interrupted. That journey from Rauris to Kolm had given me some idea of what a snow-storm in those regions meant. The avalanches caused by the weight of snow, had broken down the telephone wires, completely burying them, and, in one place, carrying them away for a distance of over two kilometres.

The *Rossknecht* had just reached Bodenhaus, but was utterly unable to push on further. It was four days before all my cases could be brought on to Kolm; and then the men had to carry them on their backs. Here was I, cut off from the world, snowed up at Kolm, and with little apparent prospect of getting to the Sonnblick; the snow falling faster and faster for four whole days, without intermission. But I was thankful enough to have reached there, for the valley beneath was laid waste with avalanches, making the roads impassable. However, the five days in which I was blockaded at Kolm were anything but wearisome. I could well have undergone a longer imprisonment with a companion so ingenious and intelligent as Rojacher. He had always some interesting subject to discuss, or new problem to set concerning the Tauern range. What perhaps interested me the most were his descriptions of winter life in this inhospitable altitude—its pleasures and difficulties, and particularly his explanation of the *Lahnen*, the local word for avalanches.

There are two kinds of *Lahnen*, he explained, *Windlahnen* or *Windsbretter* (wind avalanches), and *Jauk* or *Grundlahnen* (ground avalanches). The first belong exclusively to winter; the second to spring. These last are the avalanches of which people who live far out of the reach of avalanches have formed the one and sole idea of their nature and composition, thus confounding the two. They are, however, totally different.

The action of the ground, or *Jauk, lahn*, as its name denotes, is to break away from its base on the ground; and, as its second name denotes, mostly in consequence of warmer temperature, *i.e. Jauk*, south wind. It is composed of a huge mass of melting snow saturated with thaw water, that, restrained by the enormous friction of the earth, carries slowly along with it everything that impedes its course. It is set in motion when the moisture of the thawing ground has sufficiently diminished the earth's friction which has hitherto held it back. It needs no propelling medium; its own weight causes it to slide. The prevailing idea that any small particles of snow set primarily rolling by a bird, or any such unimportant agency, can gradually increase to the dimensions of an avalanche, is a pure fallacy. The rolling is a secondary matter; the primary agent in an avalanche is its sliding. They travel slowly, Rojacher said—that is, there is mostly time for escape on first hearing the roar of the heavy falling mass; with the *Windlahn* is no such hope, as both Rojacher, and all others whom I questioned, assured me.

The *Windlahn* he explained in the following manner. The first falls of winter snow fill up all inequalities of the surface. If it lies for a time, it consolidates and forms an even, slippery surface. More snow falling upon this smooth surface has a tendency, by its own weight, to slide off. This is certain to occur if after a heavy fall of snow the new layer has acquired such weight that its pressure overcomes the slight resistance of the underlying stratum, and any chance obstacles that hold it back. As soon as the top pressure is great enough to start a fissure, the

[1] By Dr. J. M. Pernter, of the Imperial Academy of Sciences in Vienna.

whole mass of the fresh-fallen snow sweeps with the velocity of the wind from off the slippery surface beneath. That is a *Windsbrett*, or *Windlahn*; so called, not that it is caused by the wind, but that in its headlong passage its velocity creates a storm wind which in its turn commits ravages and devastation far beyond the range of the falling avalanche.

I had many opportunities, while at Kolm and on the Sonnblick, of witnessing those terrible avalanches. During the night of February 4-5, a *Windsbrett* fell from Bucheben, filling the whole valley beneath for a distance of two kilometrés with 13 feet of snow. The avalanche itself could not force its way up the side of the opposite mountain, but the wind caused by it unroofed a farmhouse, 650 feet above the valley, and blew in the windows.

The day I started for the Sonnblick, a *Windsbrett* parted from the Hoch Narr Glacier, causing such a terrific gale of wind in Kolm that the people were in terror of their lives. The next day we looked down from the Sonnblick on the snow-field whence the avalanche had parted, and Rojacher and his assistant, Peter Lechner, estimated its length and breadth at 650 feet, and depth 13 feet, representing a fallen mass of at least 160,000 cubic metres.

One peculiarity of wind avalanches, that makes them such a special danger to tourists, is that it is so easy to start one unawares. On an inclined, slippery surface of hardened snow, there lies a thick superstratum of fresh-fallen snow, ready, so to speak, to slip away at any moment. It often requires but the weight of one man, and there are generally at least two, to produce the slight pressure that sets loose the avalanche. In such a case there is heard a dull thundering crack, immediately after which, either the mass of snow starts, in which case the men are borne down on it with the swiftness of the wind, seldom to be seen again; or, after the first crack, the mass remains stationary, the *Windsbrett* has "settled," and the travellers proceed scatheless on their way.

I underwent such an experience during my ascent of the Sonnblick, not without considerable alarm, I must confess. Not far from the miner's lodge, at about 7550 feet of altitude, we had to cross a snow-field on a considerable incline. There were fifteen of us, with Rojacher and myself. Arrived at the middle of the incline, we heard a terrific muffled crack. We had started the *Windsbrett*. For a moment we knew not whether to go on or go back, the next we found that we had escaped with the fright—the avalanche had "settled."

It is not easy to say what are the causes that hold back an avalanche once started. It seems as if the "settling" of a *Windsbrett* only occurs when passed along at its topmost end; at any rate, prudence suggests that it is the only safe path to cross one; for, in the event of its giving way, the best hope of safety is to be on the highest point of the falling mass; there is, at least, the possibility of being able to obtain a foothold above, and thus of not being crushed by the on-coming snow. Should the *Windsbrett*, after being started, remain stationary, it is in all probability due to the fact that the lower part of the snow-field is too massive to be set in motion by the unsettlement of the upper portion, and therefore does not partake in the movement. Thus the former "settles."

The account above given of *Windsbretter* will explain why the inhabitants of the regions where they are to be met with maintain that it is next to impossible to escape with life from them. Once hear the fatal crash, the avalanche is upon them, and there is no escaping from it. Their advice is, to throw oneself prostrate, with hands outstretched, if possible behind some rock or boulder; there is the chance that the *Windsbrett* may pass over him, and if buried in the snow, one would be in the most favourable position to breathe, and therefore stand the best chance of being dug out alive; while to stand upright would be, to a certainty, to be carried with it. There were many such cases among Rojacher's people during my stay on the Sonnblick. This and similar talk made the time pass agreeably enough while I was waiting at Kolm.

While thus employing ourselves, Rojacher spoke through the telephone from time to time to his men in the station (Berghaus), 7870 feet above, asking if some thirteen or fourteen of them could venture down to take up my cases. For the first four days, the invariable answer was that there was too great danger of avalanches to undertake the descent; on the fifth day at noon they decided to venture down upon their *Knappenrossen*.[1] Barely an hour after we saw them come tearing down the declivity behind the Kolm house, or rather saw but a thick cloud of snow coming towards us, amid which an occasional hat, or alpenstock, was discernible. After the men had well warmed themselves, and had invigorated themselves with draughts of hot wine, my traps were distributed among them, and at 3 o'clock we started for the station. Our ascent was effected by means of snow-shoes, we keeping carefully to the rut made by the men on their passage down. There were no deviations, the snow had so completely filled up all uneven places, covering rocks and stones with its thick mantle, that it was one straight path. Our ascent was comparatively easy, and in three hours we had reached the Miner's House (*Knappenhaus*), after having, as already related, had a considerable panic from a *Windsbrett* some twenty minutes before.

The weather, which had, so far, been tolerably favourable, had changed for the worse during the night, and I expressed my fears to Rojacher in the morning, that we should be snowed up there for some days. But his calm reply was, "Once so far, we must reach the Sonnblick before dusk, cost what it may." To my objection that we might run the danger of avalanches, he laughingly said, experience had shown him that they had no love for him. It would be an unheard-of thing for one to travel his road. His confidence reassured me, and I made no further demur to continuing our route.

Rojacher, however, added other ten men to our escort, whose duty was to go first and tread down the snow on the way to the plateau, where he expected to find the fall had been much less heavy, and where the extra men could then load themselves with the store of wood, already stacked, for the use of the house on the Sonnblick. Our party now assumed a somewhat droll appearance, marching along in Indian file, across the vast snow-fields. During the whole way to the top we were enveloped in a dense mist; and our ascent through the stupendous masses of fresh-fallen snow, was a very slow one. The first man, the pioneer, sank up to his hips at every step, despite the snow-shoes; in five minutes his strength was exhausted and he fell out, taking his place as the last but one; I always remaining the twenty-fifth man, which made the ascent comparatively easy to me. As each man placed his left foot exactly in the left foot-print of the one who preceded him, and his right foot in the right foot-print, I, as last man, had firm ground to tread, my one care being to plant my feet well into those spaces, and thus I reached the summit but little fatigued. We had taken four hours to make the ascent; and it had enabled me to form some idea of the incredible bulk of snow that can collect on the Hochgebirge. Even on the upper plateau, the snow of the last four to six days had reached a depth of ten feet. This was proved to us, on coming up to the wood-stack. It had been carried up before the last snow-fall, and stacked to a height of about ten feet. Fortunately the men had had the foresight to mark the spot by an upright pole; without this landmark we should never have found

[1] Miner's sledges, formed of stout boards on runners.

it, for the wood was completely buried, and only a short length of the pole visible. Even Rojacher had not foreseen this, he being convinced that falls of snow were considerably less on the heights. So far he was right. The fall had been lighter above than below; but then below it had been almost unparalleled. To have formed an estimate of the quantity of snow that fell that winter on the Tauern, I should have needed a previous knowledge of the locality in summer; as, unfortunately, I had not that, I was obliged to content myself with Rojacher's computation at various points. The deepest level we could see, was on the lower plateau, some 8200 feet above the level of the sea, where the telephone wire stretches over a little glacier valley. Rojacher knew that this wire was carried 66 feet above ground in the deepest part of the valley. On passing by it, we found that the snow not only reached to the wire, but that the valley had become one even snow-field; thus proving a depth of 66 feet in that part. It is unnecessary to give further instances; no description could afford a true idea of the stupendous masses of snow. They must have been seen to be believed. Rojacher repeatedly said how glad he was that a Vienna Professor should have had the experience; and even went so far, in his good-natured raillery, as to wish that—without prejudice to my scientific researches—I might taste to the full the meaning of a severe winter on those heights.

His wish was granted, even beyond his desires, for I spent a February such as had never been known before, not only as regards snow and avalanches, but of destructive storm and variations of temperature. However, although I could have desired finer weather for my investigations, my stay on the Sonnblick was most enjoyable. The mountain sickness, from which I had hitherto always suffered severely, was very slight, and of not above three days' duration. My provisions were good, and lasted out excellently. In fact, I came to the conclusion, as far as health was concerned, that my winter expedition on the Sonnblick suited me infinitely better than a month in the Riviera would have done.

Shortly before I had started on my expedition there had been such accounts in the Vienna papers of the suffering from cold experienced by the man in charge on the Sonnblick, that I expressed some fears whether I should be able to stand the extreme cold in the house. Experience soon set those fears at rest. Our rooms were most comfortably warmed; the heating apparatus is perfect; indeed we had more than once to open a window to let out the hot air. It is quite a fallacy to suppose that one cannot keep warm on the Sonnblick.

These few remarks may serve to show those to whom their *café*, daily paper, *tarok*, or whist club are not matters of vital importance, that a winter sojourn on the Sonnblick has no great difficulties—when once they get there. As for occupation, there need be no lack; at any rate, so I found. On fine days, of which I counted but nine in the four weeks, I could barely give myself time to eat or sleep; they being entirely devoted to the specific objects of my investigations. On wet ones, I had enough to do examining and verifying the meteorological instruments belonging to the Observatory; and in initiating its solitary occupant, Peter Lechner, still further into their uses. The results of my observations have been since reported to the Imperial Academy of Sciences in Vienna.

It was no light work to get my apparatus suitably adjusted, all my observations having had to be made in the open air; and it is thanks to the skill and indefatigable energy of "the Hermit of the Sonnblick"[1] that I succeeded so well. Lechner is a most devoted servant of science, and carries out all his duties on that solitary peak in the most conscientious manner. He assisted me too in my observations on the radiation of the earth, and the sparkle of the stars. As these required to be made at night, the cold rendered it necessary to be well protected with fur-lined boots, fur travelling coat, fur gaiters and fur cap, well down over the ears; otherwise I could not have withstood those nights, standing and sitting, as we often required to do for hours, in a temperature of $-4°$ F.

The simultaneity of my observations with those of Dr. Trabert were certified by the telephone, which acted admirably. The day after I arrived on the Sonnblick, the interruption between Kolm and Rauris had been repaired, and from that time there was only one day when connection was broken again—that time, unfortunately, between the Sonnblick and Berghaus, so that we were quite cut off. The next day, however, the point of breakage was found, and connection made again. It is no little difficulty to find out the point of breakage on such a height, and when the whole wire is buried under the snow.

Herr Rojacher has found a method, I do not know if in use elsewhere—anyway he found it out for himself. It is, of course, known to electricians that two near telephone stations can speak with each other if instead of one of the earth plates, connection is effected by means of any large mass of metal, as a stove, for instance, with which one of the telephones is connected. By analogy it ought also to be known (I do not know if it is) that in the case of three stations, as Kolm, Bodenhaus, and Rauris, should there be an interruption between Bodenhaus and Rauris, if that interruption has occurred near Rauris, Kolm and Bodenhaus would still be able to speak together, although, through the want of the ground conductor, there is no closed circuit. I have made that experiment myself. Now the above-mentioned larger mass of metal can be made to replace the wire from Bodenhaus to the point of interruption, supposing the wire to be long enough. It was on this last hypothesis that Rojacher founded his method—that of seeking the point where communication ceases up in the snow-fields. Taking a hand telephone with him, he starts from one of the stations between which communication is interrupted, and connects the hand telephone with the wire at one of the *Untersuchungstangen* (test poles) that are placed at intervals, and through which the wire passes, thus raised in triangular form out of the snow. As long as he can still speak with the station whence he has come he knows that the breakage has occurred farther on. When he can no longer speak he fixes a trumpet on to the telephone; if the answer, also spoken through a trumpet, be audible, the point of breakage is not far off. If the trumpet tone reaches his ear no longer, the spot is close, and a little examination enables connection to be re-established. Only by this method could connection be as quickly restored under difficulties so immense; and it is by this means that Rojacher is enabled to send out regular meteorological observations, with scarce a break, through an electrical aparatus perhaps the most perilously placed in the world.

During my stay on the Sonnblick I had opportunity to witness many rare atmospheric effects; and to become more closely acquainted with meteorological phenomena at that altitude. The second day I was there I saw a splendid sight. A white mist enveloped the whole base of the mountain up to within 500 feet of the summit; the shadow of the house on the Sonnblick being clearly projected on it. Suddenly the shadow was surrounded by a

[1] Alone for the most part throughout the year, cut off from all intercourse during the worst of the winter months, his occupation is to speak through the telephone three times daily, to record his readings on the maximum and minimum thermometers, on the sunshine recorder, the psychrometer, the hygrometer, and the hygrograph, on the anemometer, the barometer, and several other instruments; he hears, besides his own voice, generally that of one of his former comrades at the Miner's House where he used to work, inquiring, "Is all well on the Sonnblick?" And then the former silence is resumed.—Translator's note, from *Standard* of December 18, 1889.

triple rainbow of dazzling brightness. Had I not known that my eye was the centre of the exquisite sight, I must have judged the house, or rather its shadow, to be its central point. This I disproved by moving from east to west of the house, when the whole "glory" seemed displaced. I did not succeed in projecting my own shadow upon the mist, and in producing the effect myself; the "glory" remained attached to the shadow thrown by the house. I observed the same atmospheric effect several times afterwards while there, but never with such brilliancy. Another time I was struck on observing a magnificent ring round the sun, accompanied by other lesser rings. The sun was then in the east, about 14° above the horizon, and exactly over the peak of the Kleinen Sonnblick, at no great distance. The solar ring was 23½° radius, and of indescribably brilliant prismatic colours. At both extremities of the horizontal diameter was a lesser coloured sun of radiant brightness; but the strangest part of it was that I could see the lower portion of the vertical diameter of the solar ring, although it was more than 7° below the horizon. And now there appeared a lesser sun of dazzlingly white appearance, seeming as though rising behind the mountain peak; its dazzling whiteness rayed out high up into the heavens, forming, as it were, a column of light resting upon the Kleinen Sonnblick. On passing a horizontal line through this white secondary sun below the horizon, I found at a distance of 23½° to right and left of it, two coloured lesser suns, which, being also below the horizon, were projected on to the snow-fields of the Kleinen Sonnblick, and of the Goldberg-Spitze, forming a magical effect—indeed, the whole spectacle was one of entrancing beauty.

One lovely moonlight night, I was standing in front of the house, making observations with the scintillometer. After a time I was conscious of a series of rapid obscurations flitting over the field of my telescope. Looking up irritably, I perceived that small portions of the mist, which reached almost to the summit of the mountain, were being detached and borne swiftly over my head. My irritation, however, was quickly dispelled on looking at the moon through these icy veils of mist. Whenever a fleecy cloudlet passed between the moon and me, there was a gleam and lustre of rainbow hue with such intense brilliancy of the lunar surface that I had never seen the like before. I leave my readers to imagine the effect of this ever-changing moon, now of silver lustre, now iridescent with many-coloured rings, and they will understand that I quite forgot my interrupted observations in the absorbing sight.

The zodiacal light I saw there also, and more brilliantly than ever before. I cannot do better than recommend any one who is a lover of aërial effects to pass a winter on the Sonnblick. And perhaps the finest sight of all is the magnificent view—the grand panorama to be seen from such a height. The view from the Sonnblick, even on a fine summer's day, must be a sufficient reward for the toil of the ascent; on a fine day in winter it surpasses all description. The clearly marked horizon, on which there is no trace of mist or haze, the mountain ridges, even to the most remote, standing out in lines of perfect distinctness from the sky—the grandeur of the whole snow-clad scene is so overwhelming, that I could but express my surprise to Rojacher and his assistant, that no members of the Alpine Club had availed themselves of the hospitality of the house on the Sonnblick, to know and enjoy the delights of a fine winter's day on the Hochgebirge. Formerly the difficulty would have been that without shelter one could only have stayed a few minutes on the summit, and had the weather been unfavourable in those few minutes, the whole ascent would have been fruitless. But now that there is shelter on the summit, and a house so comfortably arranged, the whole difficulty is done away with. I have a strong conviction, moreover, that the ascent in winter is easier than in summer—given a normal winter with average snow-fall. It is far less fatigue to ascend steep places and cross glaciers on a moderate layer of new-fallen snow; one does not become so heated, and consequently breathing is not so difficult as in summer. And then, the infinitely finer view.

I am convinced that it can only be the inconvenience of leaving their business or professional callings at that busy season that has hitherto kept men back. So fascinated was I with the view, that I determined to advise all whose duties would permit them to pass a few winter days on the Sonnblick—the more surely that I can vouch for Herr Rojacher's hospitality removing all doubts on that score.

If phenomena of light most pleased the eye, other meteorological conditions gave me fuller scope for observation. In the first place, the height of the clouds. For the most part, unluckily, we were in them. Often we were above them, and had then the grand sight of the vast sea of cloud surging and swaying beneath us, now rising, now falling, called *Nebel boden* or *Boden nebel*. Several times, for days together, only those mountains whose peaks were higher than 8200 feet rose above the clouds; and we would be walking about in bright sunshine, while the valleys beneath were filled with cloud. At other times the northern valleys would be quite clear, and the southern ones full of cloud, or *vice versâ*. One evening we had the southern valleys a mass of cloud, the next morning, on looking out, they were perfectly clear, and the northern ones were thickly enveloped. It was as if the clouds had travelled over the Alps in the night from south to north.

With the exception of the cirri, I never saw clouds above us. These are easily traced to their source from the Sonnblick. They were more unwelcome to me even than the mist; they disturbed my observations to such an extent.

It is known that the cirri take their rise from the depression centres. Thus they were serviceable to me in determining the situation of the minimum pressure of the air. Nearly the whole of my stay on the Sonnblick depressions formed with curious persistency over the Tyrrhenian sea, passing over southwards. This was distinguishable to us by a heavy bank of cloud in the extreme south-west, whence the cirrus bands stretched out in our direction. With a change of depression to south-east, or east, the radiating point of the cirri shifted accordingly. We had nothing to fear from the southern depression; in fact, it in no way affected the weather on the Sonnblick. But if the cirri rose from the north-west, although from the extreme distance the heavy cloud bank was not visible to us, none the less were we certain within six to twelve hours that storm and mist would be the invariable consequences.

In the many violent storms I witnessed there, I directed my attention chiefly to two questions: Do the winds blow in gusts here on the summits of mountains, standing free as they do in the atmosphere? and What is the relation of the gusty winds to the "pumping" of the barometer? I had formerly been somewhat of opinion that on these free heights there was no sufficient cause for storms to blow in gusts; and in fact in storms from the south-west the gusts appeared to me to be considerably less than in Vienna, although fully perceptible. But with a gale from the north they far exceeded in violence anything on a lower level. I have no time to go more closely into this question, and will only briefly describe those of my observations which bear upon the "pumping" ("oscillations") of barometers during a storm. It is a subject that has been much under discussion of late; I will confine myself to my observations. I made use of four instruments—a mercurial barometer, a very fine Naudet's aneroid, a Richard's

barograph, and a Redier's barograph. My observations, made alternately with these four, came to the same result. If the wind appeared to have lulled for a short time, there would be a sudden fall in the barometer of often more than two millimetres. A violent gust would then follow on the fall in the barometer, its strength varying in proportion to the fall of the barometer. During the gust the barometer would rise nearly as much as it had previously fallen.

From these observations, carried on through whole days, and often far into the night, it seemed to me that the cause of the gusts must be that slight, quickly passing depressions were over us.

If these observations are correct, and I can hardly doubt them, the suction of the wind is of secondary importance in considering the causes of the "pumping" ("oscillations").

I cannot allow myself to enter into all the interesting meteorological subjects that there presented themselves, and my views upon them, without trespassing too largely on the space assigned to me in these pages. I would only refer briefly to what I observed of the marked electrical activity in the telephone. It may seem strange to speak of a strong electrical development in winter, and I must confess to have been surprised on many days to hear a loud crackling at the telephone, so loud that it was almost impossible to speak through it. Still more astonished was I to see electric sparks going off from the electric plate ("*Blitz Platte*"). Unfortunately I had not time to examine this increased electric activity in its relation to the weather; but I fancied that a fall of snow with a south wind had most influence upon it. I requested Lechner to make daily observations of the crackling in the telephone, at a given hour, and to register the four stages—weak = 1, moderate = 2, strong = 3, electric sparks = 4. I have heard from him that he has been recording his observations five times a day, and, he thinks, with good result. A prolonged series of observations will easily determine its cause.

From these hastily collected extracts of my experiments and investigations on the Sonnblick, all must be satisfied of what great importance to science is the Observatory on its summit, and not less to Alpinists. It matters little how highly I prize it; my aim is to make its value known in wider circles.

But it behoves us, scientific men and tourists, not merely to wax enthusiastic over the Sonnblick Observatory, but to take measures to ensure its permanency. I am aware that the Alpine Club has already done its part,[1] and do not doubt but that in future it will shrink from no sacrifice to uphold and support this, its foster child, which, in conjunction with the Meteorological Society, it has brought into life. But I am inclined to think that there are nearer supporters of this our most important mountain Observatory, on whom there exists a prior claim. I am under the impression that certain influential members of the Alpine Club had been called upon to form a special Sonnblick Verein, part scientific, part tourist, who by a small yearly subscription should ensure the keeping up of this invaluable station.

My descent from the Sonnblick began on March 4, amid a storm of north wind, mist, and temperature at −22° F. We rode down on miners' sledges (*Knappenrossen*), but even then had great difficulty in forcing a passage, snow having fallen knee-deep overnight. We often had to call a halt, and wade through the snow, thereby causing great delay; it took us two hours to reach Kolm, a distance usually accomplished in one.

On March 5 I reached Rauris; leaving on the 6th with Dr. Trabert for Lend. Even on these two last days, the weather followed us with unremitting severity. The way from Kolm to Rauris had been made under a heavy snowfall; and in the night of the 5th–6th there were such deep snow-drifts, that we were two hours making our way from Rauris to Landsteg.

On March 7 we reached Vienna.

[1] The corporation of the Alpine Club has just signed an agreement with Herr Rojacher, by which it guarantees him a grant of 5000 fl. towards the enlargement of the Sonnblick Observatory.

BEDFORD COLLEGE.

SOME time ago we drew attention to the fact that Bedford College, which has done so much for the education of women, was in need of funds. The new laboratories are now in use, but they are not yet paid for, and the stock of apparatus is not all that could be desired. Our readers will remember that Mr. Henry Tate had promised a donation of £1000 provided the Council could raise a like amount from other sources. We believe that the College authorities are nearly in a position to claim his generous gift; but though this will free the building itself from debt, at least £500 more is wanted to pay for equipment on a very moderate scale.

The last twelve months have been, in matters educational, a ladies' year; but the true meaning of the successes which have been won at Cambridge and elsewhere will be missed, if they are regarded only as a nine days' wonder, or as proving *ambulando* that the higher levels of undergraduate attainment can be reached by girls. The lesson which has been so strikingly enforced is that no branch of learning is the exclusive property of either sex, and that girls are wronged if we do not afford them the same opportunities for acquiring knowledge which are provided for their brothers.

The founders of Bedford College acted on this principle when it was not so widely accepted and not so self-evident as in 1890, and we can only urge on the friends of the education of women not to forget, in the hour of their triumph, the toilers who have paved the way to their success.

In an unpretending building in an uninteresting London street an effort has for long been made to supply education of the highest class for London girls. Faith in the future and effort in the present have never been wanting, even when the story of the past seemed most discouraging. The College is now undeniably a success, but it is still sadly hampered by want of means. The adequate equipment of its laboratories is surely an object for which an appeal will not be made in vain to those who believe that the benefits which science can confer will never be fully attained till a knowledge of its main principles and methods forms part of the training of all educated men and all educated women alike.

NOTES.

WE regret to have to record the death of Mr. William Kitchen Parker, F.R.S., formerly Hunterian Professor of Comparative Anatomy at the Royal College of Surgeons. Next week we hope to give some account of his services to science.

A REUTER's telegram from New York states that the remains of the Swedish inventor, John Ericsson, will be conveyed to Sweden by one of the two new American war-vessels, *Baltimore* and *Philadelphia*.

THE Dutch Academy of Sciences in Haarlem has offered a gold medal of the value of 150 gulden for the best work in each of the following subjects:—(1) Researches on the part played by bacteria in the decomposition and formation of nitrogenous compounds in various kinds of soil; (2) Microscopic investigation of the mode in which different parts of plants can unite with one another, and especially the phenomena which accompany healing after the operation of grafting. The papers must be written in German, Dutch, or Latin (not in the handwriting of the author), and must be forwarded to Dr. J. Bosseka, Haarlem, by January 1, 1891.

The list of Civil List pensions granted during the year ended June 20, 1890, includes the name of Dr. William Huggins, to whom has been awarded a pension of £150. As we have already noted, a pension of £50 has been granted to Mrs. Jane Eleanor Wood, widow of the Rev. J. G. Wood, and a pension of £20 each to the four unmarried daughters of the late Rev. M. J. Berkeley, F.R.S.

Mr. David S. Capper, Assoc.M.Inst.C.E., has been elected to the Professorship of Mechanical Engineering at King's College, London.

The annual meeting of the Botanical Society of Italy will take place in Verona during the month of September.

French papers announce the death of M. Paul Loye, at the early age of 29. He was the author of a memoir on the physiology of death by decapitation, and had published many short notes on physiological questions. He had for some time been engaged in an elaborate study of the excretory functions of birds, concerning which he had collected many facts. M. Loye was assistant to Prof. Brouardel, and *Maître de Conférences* in the Faculty of Sciences of Paris, and had been Paul Bert's last assistant.

The death of M. Alphonse Favre, at the age of 77, is announced. He was formerly Professor of Geology at Geneva, and was recognized as an authority on the geology of the Alps.

The half-yearly general meeting of the Scottish Meteorological Society was held in Edinburgh on Monday, July 14. Lord McLaren presided. The following was the programme of business:—(1) Report from the Council of the Society; (2) address by the Chairman on the high and low level observatories of Ben Nevis; (3) on the meteorological conditions of desert regions, with special reference to the Sahara, by Dr. John Murray. In their report the Council express sincere regret at the death of Dr. James Stark, who long held the office of Superintendent of the Statistical Department in the Register House, Edinburgh, and gave very effective aid in founding the Society. The self-recording instruments, furnished by the Meteorological Council for the low level observatory at Fort William, arrived at the end of June, and it is contemplated that the regular work of recording the continuous observations will begin in August. The observations which have been carried on in Fort William by Mr. Livingstone in connection with those made at the top of Ben Nevis will be continued at least till the New Year, in order that a comparison may be made with them and the similar eye-observations made by Mr. Omond at the Observatory adjoining. It is arranged that Dr. Buchan's time will be wholly given, during next year, to the examination and discussion of the observations of the Ben Nevis observatories. In connection with this difficult and laborious undertaking, Mr. Omond will receive from the Meteorological Council three copies of their daily and weekly weather maps, on which he will enter certain of the meteorological data from the high and low level observatories, together with occasional remarks that may from time to time strike him as bearing more particularly on forecasting weather. The weather maps give two daily representations, with remarks, of the weather of Europe at 8 a.m. and 6 p.m. Thereafter, one of the three sets of maps will be sent to the Society's Office, the second to the Meteorological Office of London, and the third will be retained by Mr. Omond.

The Council also refer to the observations of Mr. Rankin on the number of dust particles in the atmosphere, carried on with the two sets of apparatus invented by Mr. Aitken. Though it would be premature to offer a statement of positive results, the Council think that some interesting conclusions appear to be indicated by the observations. The maximum number of dust particles in a cubic centimetre hitherto observed is 12,862, on March 31, and the minimum 50, on June 15. On March 31, at 4.30 p.m., the summit was clear, and the number of particles was 2785, but shortly thereafter a thickness was seen approaching from south-west, which by 6 p.m. reached the Observatory, and the number of particles rose to 12,862. On June 15 many observations were made during the day, when the number of particles fell from 937 at midnight to 50 at 10.30 and 11.42 a.m. The observations point to a daily maximum during the afternoon minimum barometer, and a minimum during the morning minimum barometer—these being probably intimately connected with the diurnal ascending and descending currents of the atmosphere. Interesting intimate relations are also indicated between the numbers of dust particles and the cyclones and anticyclones over North-Western Europe at the time. The observations also indicate that the dust particles may vary enormously during the presence of mist or fog, without being accompanied by any difference in the apparent density of the fog. The Council consider that the inquiry is an extremely hopeful one; and in view of the relations with cyclones and anticyclones, its bearings as regards the forecasts of the weather will be very specially investigated.

For several years past it has been the practice of the Indian Meteorological Department to issue in the month of June a forecast of the prospects of the monsoon rains, based partly on the reported extent and thickness of the Himalayan snows, partly on the distribution of the atmospheric pressure, the small variations of which are found by experience to be remarkably persistent in India, and to serve as an indication of the probable strength of the monsoon, and alternatively of the prevalence of dry land winds. The forecast for the forthcoming season announces that owing to the very slight snowfall of Afghanistan, Baluchistan, and almost the whole of the Himalayan region, the conditions are eminently favourable for a good strong monsoon. The only unfavourable indication is that the past winter has been very severe in Yarkand, and perhaps in other distant parts of Central Asia. The pressure is unusually low this year in Bengal, and above the average in Central India and the northern half of Bombay, and the local pressure conditions considerably resemble those of 1876. It is therefore considered probable that while the eastern half of the Ganges valley, Assam, and Burma will receive early and abundant rain, the rains may be late and scanty over a considerable area of North-Western India.

The Rev. E. Colin, S.J., Director of the newly-established Royal Observatory of Madagascar, at Tananarivo, has published the monthly results of meteorological observations at that place during 1889. As observations for Madagascar are scanty, we are glad to learn that observations are now taken at four stations in various parts of the island, and that others will shortly be established. The maximum temperature at Tananarivo, 87°·4, occurred on November 14, and the minimum, 41°·0, on July 31. Rain fell on 89 days; by far the greatest quantity falls between November and March. None fell in May 1889. The prevalent wind direction is between south-east and north-east. The Report contains summaries for the three other stations referred to, during 1889, and for Tananarivo from 1872–88. Some of the latter have never been published before, and form an important addition to our knowledge, but, having been made by various persons, may not be so trustworthy as those made at the Observatory.

The meeting lately held at the Mansion House, under the presidency of the Lord Mayor, for the furtherance of the International Congress of Hygiene, which will assemble in London in 1891, was attended by many influential medical men and students of sanitary science. Sir Douglas Galton explained the

object and organization of the Congress, to which delegates had been already appointed by all the leading Societies of Great Britain and of the Continent. He mentioned that in any case the cost of the Congress would be considerable—probably not less than £5000—and that an appeal would be made to raise the required funds and to make the gathering worthy of Great Britain. Among the subsequent speakers were Lord Wantage, Prof. Humphry, Mr. Ernest Hart, Sir Spencer Wells, Sir Henry Thompson, and Dr. Thorne Thorne. The organizing committee is now taking steps to raise a sum of at least £5000, and no doubt its appeal will receive a liberal response from some of the great Societies and Corporations as well as from private individuals.

IN order to make the Parkes Museum, which is supported by the Sanitary Institute, available to all classes for the purpose of obtaining information on matters relating to hygiene and sanitary appliances, the Council have resolved to throw the Museum open free at all times except when meetings are being held.

THE Medical Academy for Women at St. Petersburg is to be reopened. At its sitting of June 9, the municipality of that city voted a yearly grant of £3000 for the support of the Academy, and decided to give it the use of a house belonging to the municipality, and to open the city hospitals to the students. Private subscriptions fully guarantee the further existence of the Academy. It is hoped, therefore, that the Government will not oppose the reopening of the institution, which has already given to Russia no fewer than 698 lady doctors. The decision of the municipality was based upon a report by Dr. Archangelsky, who speaks very favourably of the work done by the eleven lady doctors who are in the employment of the municipality for the inspection of city schools and the poorer districts of St. Petersburg.

THE joint meeting of the Essex Field Club and the Gilbert Club, held at Colchester on July 5, proved a great success in spite of the continuous downpour of rain which lasted throughout the day. Over fifty members of the two Societies assembled at 11.30 in the Castle Museum, where the Hon. Curator, the Rev. C. L. Acland, and Mr. H. Laver pointed out the objects of interest to the visitors. The party then visited Holy Trinity Church, wherein lie the remains of Gilbert, and which contains a mural tablet erected to his memory by his brothers. After inspecting the house in which Gilbert was born, and other places of local interest, the visitors adjourned to luncheon at the Red Lion Hotel, the chair being taken by Lord Rayleigh, who was supported by the Mayor of Colchester, the President of the Essex Field Club, and many well-known men of science and local residents. Among those present were Profs. D. E. Hughes, F.R.S., G. D. Liveing, F.R.S., J. Perry, F.R.S., R. Meldola, F.R S., and S. P. Thompson, Messrs. G. Kapp, J. Paxman, Conrad Cooke, and F. H. Varley. The Chairman made a short speech, in the course of which he alluded to the importance of Gilbert's work, and pointed out that, although it is to Gilbert that we are indebted for the theory that the earth is a great magnet, we are not much in advance of this position at the present time, as nobody has yet explained the origin of terrestrial magnetism. The Mayor of Colchester then took the opportunity of welcoming the two Societies to the town on the part of the inhabitants. After luncheon some of the party drove to the Vale of Dedham, rendered famous in art by the paintings of Constable, who was born at Flatford Mill in this district. In the evening a reception was given at the Town Hall by the Mayor and Mayoress. Many electrical novelties were exhibited, and an incandescent light installation was supplied from premises on the other side of the road, where plant had been erected by Messrs. Christy, Son, and Norris, of Chelmsford. An interesting piece of apparatus, constructed on the pattern of Crookes's radiometer, but working in air instead of in a vacuum, was exhibited by its inventor, Mr. C. E. Benham, who attributed its rotation to the action of convection currents. There were also on view exhibits by Messrs. Crompton, of Chelmsford, lathes and sewing-machines worked by an electric motor, and other objects of interest. Prof. S. P. Thompson delivered an interesting lecture on the early magnetic experiments of Gilbert, illustrating his subject by experiments shown with the projecting lantern. A vote of thanks was proposed by the Mayor, and seconded by Mr. J. Paxman, who remarked that he should like to see Gilbert honoured not only by a statue in his native town but also in a more useful way, such as by the foundation of a Gilbert Scholarship in connection with one of the Universities. A vote of thanks was proposed by Prof. Meldola on behalf of both the Clubs to the Mayor and Mayoress, to Dr. Laver, and Mr. J. C. Shenstone, all of whom had by their exertions contributed to the success of the day's proceedings.

IN a paper on ornithophilous flowers,[1] contributed to the *Annals of Botany*, Mr. G. F. Scott-Elliot records the very interesting observation that the Cinnyridæ or sun-birds, which play an important part in the fertilization of flowers in South Africa, have the same habit as the Apidæ in other countries—that is, of not "mixing their honey," but, on the same journey, confining their visits pretty much to the same species of flower. The species of sun-birds which are especially good fertilizers in South Africa are *Nectarinia chalybea*, *N. bicollaris*, and *Promerops caper*. In accordance with the view of Darwin, but opposed to that of Wallace, Mr. Scott-Elliot believes that the identity of colour (an unusual shade of red) in the majority of ornithophilous flowers and on the breasts of species of *Cinnyris* is an important element in pollination by birds.

A NEW little magazine, which ought to be of service to those who devote attention to questions relating to manual training, has just been started. It is called *Sloyd or Hand-Craft*. Its primary object is to acquaint the members of the Home Sloyd Union, and all those who are interested in the development of a distinctively English form of manual instruction, with the progress of the Sloyd system as practised in this country. But it is by no means intended to exclude what is being done in other directions for the purpose of making education more practical by means of hand and eye training, more especially as regards children from eleven to fifteen years of age.

BY an Order in Council, dated June 30, 1890, which has been issued as a Parliamentary paper, it is prescribed that the following monuments in Ireland shall be deemed to be ancient monuments to which the Ancient Monuments Protection Act, 1882, applies:—

Monument.	County.	Parish.
(1) Cahernamactierech and Bee Hive Structures on the Promontory of Dingle ...	Kerry ...	Drumquim and Ballinroher.
(2) Round Tower, Lusk	Dublin ...	Swords.
(3) Round Tower, Kells	Meath ...	Kells.
(4) Stone Cashel with Galleries ...	Sligo	Cashelmore.
(5) Stone Circles and Pillar Stones ...	Fermanagh	Enniskillen.
(6) Round Tower of Tulloheran ...	Kilkenny ...	Tulloheran.
(7) Round Tower of Rathmichael, Church and Stone Cross	Dublin ...	Rathmichael.

A Californian salmon (*Oncorhynchus quinnat*, Günther) has recently been caught in the Mediterranean, near Banyuls. Probably it found its way thither from the River Aude, into which many young fish of this species have been introduced, in the hope that they may be acclimatized in France.

A portrait of the African explorer Captain Gaetano Casati forms the frontispiece of the May number of the *Bulletin of the Italian Geographical Society*. Casati reached Cairo early in May, and letters in the *Bulletin* deal with his journey to the coast with Emin and Stanley. An itinerary of his nine years of travel shows that he left Suakin for Berber and Khartoum in January 1880. In July of the same year he started in a sailing-boat down the White Nile to Mishra-el-Rek, and thence on foot to Wau, where he met with Gessi at the end of September. He then threaded his way southwards among the feeders of the Bahr-el-Ghazal to the Congo basin, and for some time made Tangasi, on the Welle or Makua branch, a centre for exploration. Close by, at Mboro, in June 1881, he met with Dr. Junker. Finally, he made his way to Ladò, on the main stream of the White Nile; and there, at the end of March 1883, he met Emin Pasha for the first time. Thence he walked up the left bank to Wadelai, and continued the voyage up the Albert Nyanza by steam-boat. It was not until April 28, 1888, that the meeting between Emin Bey, Casati, and Stanley took place on the plateau above Kavalli to the south-west of the lake. The journey down the Semliki valley, the exploration of Lake Albert-Edward, and the return to Zanzibar, are recent history. The remaining papers of the number deal mainly with South America. The most interesting of these is that of Count Orsi di Broglia di Mombello on the sculpture of the primitive inhabitants of the Upper Orinoco. Many carvings on the stones of tombs have been discovered among the villages of this district: the sculpture is rough and fantastic, but evidently aims at reproducing certain natural objects. Thus, at the Grotto of Caicara, near the right bank of the Orinoco, many rocks carved in the primitive manner of the slate sketches of school-days, evidently exhibit an attempt to figure a tiger that is very common in this district. In neighbouring caves were found mummies closely resembling Egyptian ones; this the author regards as further evidence of the common origin of the two races, previously suggested by the striking similarity in shape of the skulls of the South American Indians and those found in the tombs of Egypt.

A Swedish Expedition to Cameroon is being arranged by the Academy of Sciences in Stockholm. The object of those who are to take part in it will be to study the fauna of the Western Cameroon Mountains, and to make scientific collections for the Academy. Herr Yngve Sjöstedt is to be in command of the Expedition, which is expected to be absent for about fifteen months.

We have received the following details of the researches in which Prof. Bastian is engaged on behalf of the Anthropological Museum of Berlin. In December last he forwarded to Berlin the results of excavations made at Tashkent; the terra-cotta vases and utensils all bearing strong evidence of Greek influence in their workmanship. During January he spent some time in Zanzibar and Mauritius, and at the latter place he was enabled to make a collection of Mascarene curiosities. From Tinivelly, in Southern India, he forwarded some bronze idols in February. March was spent at Malabar, April at Mysore, the beginning of May in Beloochistan, and the latter end of the month in Peshawar. Prof. Bastian has sent interesting ethnographical collections from all these districts.

Sir Arthur Gordon lately received from the Pandits and Buddhists of Ceylon addresses in which, among other things, he was praised for the encouragement he had given, during his term of office, to science and learning. "Your Excellency," said the Buddhists, "with the laudable wish of preserving the philosophy and sciences contained in that most noble language the Pali, which is regarded by Eastern nations as the original language and the depository of the teachings of the blessed Buddha, as well as those found in the Sanskrit—the language of the gods—has caused many works, such as the 'Mahawansa' and others, to be translated into English, and given an incentive to the publication of Pali and Sanskrit works by allowing them to be printed at the Government Press." The Pandits took occasion to express a hope that Sir Arthur might still continue to exercise his influence on their behalf:—"It is with great pleasure that, whilst we gratefully express our thanks for the benefits already received at your Excellency's hands, we at the same time seize this opportunity of begging your Excellency not to relax your efforts on behalf of our literature and archæology, but to impress upon your Excellency's successor, as well as on Her Majesty's Government, the need not only to continue, but to increase, the exertions that are now being made to preserve the recollection of our glorious past, as an incentive to our countrymen of the present day to noble aims and heroic efforts in the future."

Some discussion has been going on in Ceylon of late over the question of the language spoken by the Veddahs, the aborigines of that country. The subject (says the *Colonies and India*) would seem to be one well worthy the attention of philologists, and the brothers Sarasin, who have been pursuing their anthropological researches in Ceylon lately, express the opinion that if a philologist were to take the matter up great service would be rendered to all those engaged in the work of scientific research in the island. Tennant says of the Veddahs, "Their language, which is limited to a very few words, is a dialect of Singhalese without any admixture from the Sanskrit or Pali—a circumstance indicative of their repugnance to intercourse with strangers." Prof. Schmidt, of the Leipzig University, who visited the Veddahs last year, says, "Their language is similar in construction to the Dravidian languages—that is, similar in grammatical construction; but they have adopted a great number of Singhalese words," which enabled him to hold converse with them by means of a Singhalese interpreter. The Drs. Sarasin also managed to make themselves understood by means of Singhalese.

In the last issue of the *Records* of the Geological Survey of India, Mr. Griesbach's mission to Afghanistan is thus referred to:—"Mr. Griesbach returned to India last July. His work with the Ameer was, as is now so very largely the case in the Survey, geologico-industrial, though this was greatly retarded by unforeseen political complications in the State. During his journey in 1888, up the Logar Valley to the Khurd Kabul Valley, Upper Wardak, Cherkh, Kharwar, Zanakhan, Ghazni, &c., the most interesting geological work was the recognition of at least three horizons: the Rhætic with *Lithodendron* (in Kharwar), the Upper Jurassic (or possibly Neocomian) plan-beds near the Shutargardan; and, finally, well-developed nummulitics (in Kharwar and Shilghar). He examined the copper lodes of the Logar and Khurd Kabul areas, the magnesite of the Logar and the entrance to the Taugi Wardak, the graphite of Cherkh, the iron and lead ores of Kharwar, and the argentiferous lead ore of Zanakhan near Ghazni. It turns out, also, that the entire Upper Surkh-ab Valley from near Doab-i-Mekzari to near Dahana Iskar is practically one big coal-field with numerous thick seams of good coal of Triassic and Rhætic age."

The official Report of the survey work done towards the close of the Chin-Lushai Expedition shows, according to the Allahabad *Pioneer*, that the Boinu River, which flows only six miles

west of Haka, is undoubtedly the main stream of the Koladyne, which was so familiar in connection with General Tregear's movements. Captain Bythell, R.E., who was at first on the Chittagong side, accompanied General Symons on his tour southwards from Haka, and traced the stream to within twelve miles of where he had last seen it from the Blue Mountain side. It is satisfactory to have this confirmation of the statements sent by correspondents with the Field Force, particularly as the upper course of the Koladyne was unknown to our geographers. The total area of topography, by the way, covered by the operations of Captain Bythell's party, is put down at about five thousand square miles, while the surveyors on the Burmah side must also be credited with work on a similar scale. The new maps of the Chin-Lushai hills, when they come to be published, will no longer show those great blank spaces which have hitherto been so noticeable in the old issues.

IN Grinnell Land, at sea-level (81° 44′ N. lat.), the mean day temperature is above freezing-point from about June 13 to August 23, *i.e.* 72 days. It has been recently pointed out by Dr. Hann, that on the top of the Sonnblick, at a height of about 10,000 feet, and in 47° N. lat., the temperature returns above freezing-point about the same time (viz. June 8); but it is not till the end of September or beginning of October that it goes below that point again. On the other hand, the mean summer temperature on the Sonnblick is considerably lower than in Grinnell Land at sea-level.

BIOPHENE, , an entirely new compound intermediate between the fatty and aromatic series, and somewhat resembling thiophene in properties, has been prepared by Dr. Louis E. Levi, of the Massachusetts Institute of Technology, Boston (*Technology Quarterly*, May 1890). Thiophene, , was discovered by Prof. Victor Meyer in 1883; the discovery attracted considerable attention at the time, and has since led to the preparation of a whole series of derivatives analogous in many cases to those of benzene. Dr. Levi worked for some time in the laboratory of Prof. Meyer, and has subsequently followed up ideas then discussed, which have now resulted in the preparation of biophene. Just as thiophene is obtained by the action of phosphorus trisulphide upon succinic acid, so biophene is found to be produced by the action of trisulphide of phosphorus upon thio-diglycollic acid, $COOH—CH_2—S—CH_2—COOH$. A mixture of five grams of thio-diglycollic acid with ten grams of phosphorus trisulphide is heated, together with 15–20 c.c. of ether, in a sealed tube for two hours at a temperature of 170° C. After cooling, the end is opened at the blowpipe, when a great rush of accumulated sulphuretted hydrogen gas occurs. The contents of the tube are separated in the usual manner by means of a tap funnel, and washed with caustic potash solution. After withdrawing the alkali, the remaining oil is dissolved in ether and dried by means of fused calcium chloride. The ether is finally evaporated, and the residual oil fractionally distilled. As the result of this latter process, a liquid is eventually obtained boiling between 165° and 170°, which on analysis yields numbers agreeing with the formula of biophene, $C_4H_4S_2$. When biophene is mixed with sulphuric acid and a crystal of isatine added, a beautiful violet coloration is produced, a reaction which appears to be analogous to that of thiophene, which produces with sulphuric acid and isatine a dark blue coloration. Biophene also reacts with acid chlorides in presence of aluminium chloride like thiophene, thus with acetyl chloride aceto-bienone or bienyl acetyl ketone, $C_4H_3S_2 . CO . CH_3$, is produced, hydrochloric acid being eliminated. This ketone is a thick, heavy liquid which may be distilled in steam and possesses an aromatic odour somewhat resembling that of aceto-thienone. Heated alone aceto-bienone boils, but with decomposition, at 300°. Sunlight rapidly turns it dark brown. Aceto-bienone also reacts with phenylhydrazine with formation of a compound of the composition

$$C_4H_3S_2 . C\begin{cases} CH_3 \\ N_2HC_6H_5 \end{cases}.$$

The similarity of biophene in all the above reactions to thiophene and benzene is very striking, the replacement of two of the CH groups of benzene by sulphur not being accompanied by any very great change in chemical behaviour. The formation of biophene from thio-diglycollic acid, also affords another instance of the passage from the fatty series to bodies of aromatic properties, and biophene itself will stand as an additional link between the two series.

THE additions to the Zoological Society's Gardens during the past week include a Great Anteater (*Myrmecophaga jubata* ♀) from British Guiana, presented by the Directors of the Botanical Gardens, Demerara; an Egyptian Gazelle (*Gazella dorcas*) from Suakim, presented by Commander W. Crofton, R.N.; a Cape Ratel (*Mellivora capensis* ♀) from Suakim, presented by Captain J. F. M. Prinsep; a Jackal Buzzard (*Buteo jacal*), a —— Hawk Eagle (*Nisaetus spilogaster*) from Cape Colony, presented by Mr. W. H. Wormald; a Guillemot (*Lomvia troile*), British, presented by Mr. T. H. Nelson; a Greater Spotted Woodpecker (*Dendrocopus major*), British, presented by Mr. W. H. B. Pain; an Australian Crow (*Corvus australis*) from Australia, deposited; two Chinchillas (*Chinchilla lanigera*) from Chili, an Indian Chevrotain (*Tragulus meminna* ♂) from Ceylon, an Elate Hornbill (*Ceratogymna elata*), a White-necked Crow (*Corvus scapulatus*) from West Africa, a Large Grieved Tortoise (*Podocnemis expansa*) from the Amazon River, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on July 17 = 17h. 42m. 41s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) The spectrum of this remarkable nebula has not yet been completely examined. In 1868, Captain Herschel observed two lines in the spectrum, and, in addition, a decided continuous spectrum from the brightest point, which is "*not* stellar." These lines are stated to be ill-defined; and now that it is asserted by some observers that the nebula lines are always sharp, they should be re-examined with special reference to this point. Seeing that the brightest point is not a star, it will be well also to look for maxima of brightness in the con-

tinuous spectrum, the usual flame comparisons being employed if necessary. In the General Catalogue the following description is added:—"A very remarkable object; very bright; exceedingly large; extremely irregular figure; with large cluster." Webb refers to it as "a splendid galaxy object, visible to the naked eye."

(2) This nebula was discovered by Tuttle in 1859, and, according to D'Arrest's observations in 1863, it would appear to be variable. It is oval in shape, 2' long and 80" broad, and is said to be "pretty bright." No attempt has been made, as far as I know, to determine its spectrum, to say nothing of any variations of spectrum which may accompany the supposed changes in brilliancy.

(3) This star is one of Group II. at a very late stage. Dunér states that "the bands 2, 3, 7, 8 are visible, but they are difficult to recognize as bands, because of their little width. The spectrum is almost of the same type as that of α Tauri." A special study should be made of the lines which accompany the bands, with special reference to how they differ either in position or intensity from the darkest lines in the solar spectrum.

(4 and 5) According to Vogel, these stars have very well developed spectra of the solar type and of Group IV. respectively.

(6) The spectrum of this star is a well-marked one of Group VI., the principal bands being very wide and dark. There is possibly also a trace of band 4 (λ 589).

(7) This variable will reach a maximum about July 24. Its spectrum is of the Group II. type, and is stated by Dunér to be one of the finest in the heavens. The range of variation is small—4·3-4·6—in a period which is not yet completely determined (46? days, according to Gore). Observations similar to those suggested for other variables of the same type should be made.

A. FOWLER.

PHOTOGRAPHS AND DRAWINGS OF THE SUN.—The Memoirs of the Royal Astronomical Society, vol. xlix. Part 2, 1887-89, have just been issued, and contain, with other papers, one presented by the late Father Perry in June 1889 on the above subject.

The areas of spots derived from the solar photographs of 1887, and published in the "Greenwich Observations," have been compared with similar values computed from the measures of the drawings made at Stonyhurst College Observatory. The area computed from the photographs, however, shows a decided general excess over those obtained from the drawings. An idea of the difference may be obtained from the values of the mean daily spotted area, that for 1887 taken from the photographs being 179, while the drawings give 171.

On 29 days penumbra are found in the drawings and not in the photographs, whilst such records occur on the photographs alone only 16 times; hence the greater area obtained from the photographs cannot be explained by a failure in the drawings to record faint spots and penumbral markings.

An attempt was made to compare the faculæ recorded on the drawings and on the photographs, but unsuccessfully, owing to the enormous excess obtained from the former over that computed from the latter. To eliminate this difference Father Perry suggested that the conditions necessary to obtain good photographs of faculæ may differ from that which is best for spots, and that, therefore, a twofold series of photographs may be necessary, one for spots and the other for faculæ. Two plates, showing sun-spot drawings in 1887, from the Stonyhurst series, accompany the memoir.

OBSERVATIONS OF THE ZODIACAL LIGHT.—Prof. Arthur Searle, in *Astron. Nachr.*, No. 2976, contributes a note on zodiacal light observations made at Harvard College Observatory during the last fifty years. With respect to the permanence of the ordinary western zodiacal light, the observations support the results obtained by previous observers, viz. that it must be considered as a very permanent phenomenon, and one subject only to slight variations in its degree of visibility, apart from atmospheric causes. Another principal subject of investigation was the normal distribution of light in the zodiac and its vicinity, and it is noted that the zodiacal bands, apparently forming a prolongation of the ordinary zodiacal light, were never seen at Harvard College. A number of permanent bands or belts of faint light, however, not confined to the zodiac, although certain portions of them follow the course of the ecliptic, are described in the records. A comparatively large number of observations of the phenomena of a feeble maximum of light in opposition to the sun, commonly known as *Gegenschein*, have been obtained. Prof. Searle thinks that the photometric observations of Müller and Parkhurst, which show that as an average asteroid approaches opposition its brightness increases by about 0·03 of a magnitude for every degree by which its phase is increased, may afford an explanation of this slight maximum of light in opposition to the sun, the light being reflected in this case from the meteoritic matter dispersed through the solar system. Indeed, if the amount of light received from a meteoritic particle be supposed to increase even proportionally to its phase, a maximum appears at opposition, while the law of increase in light assumed for the asteroids, was approximately proportional to the fourth power of the phase.

RING NEBULA IN LYRA.—The current number of *Comptes rendus* (July 7) contains a note by M. G. Rayet on a photograph of this nebula obtained at Bordeaux Observatory with an exposure of three hours. The photograph shows all the stars observed near the ring by Lord Rosse in 1844; the star with the signification 3, however, is double, whereas that astronomer, and later Prof. Hall, mapped it as triple. There is also a very definite indication of a nebulous star of the 14th or 15th magnitude, almost in the centre of the ring. Although this star has been observed by many astronomers (*e.g.* Hahn, Secchi, Lassell, Schultz, and Holden) and has been photographed by Gothard, other astronomers (viz. Herschel, D'Arrest, Lord Rosse, Hall, and Vogel) have observed the nebula when the star was not visible, and it does not appear on the photographs taken by the Brothers Henry previous to 1886. M. Rayet therefore concludes that the star is variable, and hopes to make such observations and obtain such photographs as will enable him to demonstrate the fact. Stars in or near nebulæ and clusters seem from recent investigations to be more subject to variability than those not so situated.

PHOTOGRAPHS OF STELLAR SPECTRA.—In the same number of *Comptes rendus* a note occurs by Admiral Mouchez, on some photographs of stellar spectra taken by the Brothers Henry at Paris Observatory, and presented by him to the Academy. Some of the photographs were obtained by means of a prism having an angle of 45° placed in front of the object-glass of the photographic equatorial, others by means of a prism having an angle of 22°; and Admiral Mouchez remarked that, although the results represented the first attempts in this direction, they compared very favourably with those obtained in America, where work of the same nature has been carried on for some time. It is noted that the Brothers Henry attribute the fuzziness of the lines in the spectra of stars like Altair to a high velocity of rotation and a great amount of agitation at the surface. The photographs are the beginning of an investigation into the chemical composition of stars and motion in line of sight, recently begun at this Observatory.

ON THE SUPERFICIAL VISCOSITY OF WATER.[1]

THE idea that liquids are endowed with a viscosity peculiar to the surface is to be found in the writings of Descartes and Rumford; but it is to Plateau that its general acceptance is due. His observations related to the behaviour of a compass needle, turning freely upon a point, and mounted in the centre of a cylindrical glass vessel of diameter not much more than sufficient to allow freedom of movement. By means of an external magnet the needle was deflected 90° from the magnetic meridian. When all had come to rest the magnet was suddenly removed, and the time occupied by the needle in recovering its position of equilibrium, or rather in traversing an arc of 85°, was noted. The circumstances were varied in two ways: first, by a change of liquid, *e.g.*, from water to alcohol; and, secondly, by an alteration in the level of the liquid relatively to the needle. With each liquid observations were made, both when the needle rested on the surface, so as to be wetted only on the under side, and also when wholly immersed to a moderate depth. A comparison of the times required in the two cases revealed a remarkable dependence upon the nature of the liquid. With water, and most aqueous solutions, the time required upon the surface was about *double* of that in the interior; whereas, with

[1] Paper read before the Royal Society, by Lord Rayleigh, Sec.R.S., on June 5, 1890.

the liquids of Plateau's second category, alcohol, ether, oil of turpentine, &c., the time on the surface was about *half* of the time in the interior. Of liquids in the third category (from which bubbles may be blown), a solution of soap behaved in much the same manner as the distilled water of the first category. On the other hand, solutions of albumen, and notably of saponine, exercised at their surfaces an altogether abnormal resistance.

These experiments of Plateau undoubtedly establish a special property of the surface of liquids of the first and third categories; but the question remains open whether the peculiar action upon the needle is to be attributed to a viscosity in any way analogous to the ordinary internal viscosity which governs the flow through capillary tubes.

In two remarkable papers,[1] Marangoni attempts the solution of this problem, and arrives at the conclusion that Plateau's superficial viscosity may be explained as due to the operation of causes already recognized. In the case of water and other liquids of the first category, he regards the resistance experienced by the needle as mainly the result of the deformation of the meniscuses developed at the contacts on the two sides with the liquid surface. This view does not appear to me to be sound: for a deformation of a meniscus due to inertia would not involve any dissipation of energy, nor permanent resistance to the movement. But the second suggestion of Marangoni is of great importance.

On various grounds the Italian physicist concludes that "many liquids, and especially those of Plateau's third category, are covered with a superficial pellicle; and that it is to this pellicle that they owe their great superficial viscosity." After the observations of Dupré[2] and myself,[3] supported as they are by the theory of Prof. Willard Gibbs,[4] the existence of the superficial pellicle cannot be doubted; and its mode of action is thus explained by Marangoni[5]:—"The surface of a liquid, covered by a pellicle, possesses two superficial tensions; the first, which is the weaker and in constant action, is due to the pellicle; the second is in the latent state, and comes into operation only when the pellicle is ruptured. Since the latter tension exceeds the former, it follows that any force which tends to rupture the superficial pellicle upon a liquid encounters a resistance which increases with the difference of tensions between the liquid and the pellicle." In Plateau's experiment the advancing edge of the needle tends to concentrate the superficial contamination, and the retreating edge to attenuate it; the tension in front is thus inferior to the tension behind, and a force is called into operation tending to check the vibration. On a pure surface it is evident that nothing of this sort can occur, unless it be in a very subordinate degree, as the result of difference of temperature.

This is an important distinction, discussed by Willard Gibbs, according as the contamination, to which is due the lowering of tension, is merely accidentally present upon the surface, or is derived from the body of the liquid under the normal operation of chemical and capillary forces. In the latter case, that, for example, of solutions of soap and of camphor, the changes of tension which follow an extension or contraction of the surface may be of very brief duration. After a time, dependent largely upon the amount of contaminating substance present in the body of the liquid, equilibrium is restored, and the normal tension is recovered. On the other hand, in the case of a surface of water contaminated with a film of insoluble grease, the changes of tension which accompany changes of area are of a permanent character.

It is not perfectly clear how far Marangoni regarded his principle of surface elasticity as applicable to the explanation of Plateau's observations upon distilled water; but, at any rate, he applied it to the analogous problem of the effect of oil in calming ripples. It is unfortunate that this attempt at the solution of a long-standing riddle cannot be regarded as successful. He treats the surface of the sea in its normal condition as contaminated, and therefore elastic, and he supposes that, upon an elastic surface, the wind will operate efficiently. When oil is scattered upon the sea, a non-elastic surface of oil is substituted for the elastic surface of the sea, and upon this the wind acts too locally to generate waves. It is doubtless true that an excess of oil may render a water surface again inelastic; but I conceive that the real explanation of the phenomenon is to be found by a precisely opposite application of Marangoni's principle, as in the theories of Reynolds (Brit. Assoc. Rep., 1880) and Aitken (Edinburgh Roy. Soc. Proc., 1882-83, vol. xii. p. 56). Marangoni was, perhaps, insufficiently alive to the importance of *varying degrees* of contamination. An ordinary water surface is indeed more or less contaminated; and on that account is the less, and not the more, easily agitated by wind. The effect of a special oiling is, in general, to increase the contamination and the elasticity dependent thereupon, and stops short of the point at which, on account of saturation, elasticity would again disappear. The more elastic surface refuses to submit itself to the local variations of area required for the transmission of waves in a normal manner. It behaves rather as a flexible but inextensible membrane would do, and, by its drag upon the water underneath, hampers the free production and propagation of waves.

The question whether the effects observed by Plateau upon the surface of distilled water are, or are not, due to contamination must, I suppose, be regarded as still undecided. Oberbeck, who has experimented on the lines of Plateau, thus sums up his discussion:—"Wir müssen daher schliessen, entweder, dass der freien Wasseroberfläche ein recht bedeutender Oberflächenwiderstand zukommt, oder dass eine reine Wasseroberfläche in Berührung mit der Luft überhaupt nicht existirt" (*Wiedemann's Annalen*, vol. xi. 1880, p. 650).

Postponing for the moment the question of the origin of "superficial viscosity," let us consider its character. A liquid surface is capable of two kinds of deformation, dilatation (positive or negative) and shearing; and the question at once presents itself, Is it the former or the latter which evokes the special resistance? Towards the answer of this question Marangoni himself made an important contribution in the earlier of the memoirs cited. He found (p. 245) that the substitution for the elongated needle of Plateau of a circular disk of thin brass turning upon its centre almost obliterated the distinction between liquids of the two first categories. The ratio of the superficial to the internal viscosity was now even greater for ether than for water. From this we may infer that the special superficial viscosity of water is not called into play by the motions of the surface due to the rotation of the disk, which are obviously of the nature of shearing.

A varied form of this experiment is still more significant. I have reduced the metal in contact with the water surface to a simple (2") ring, ACBD, of thin brass wire (Fig. 1). This is

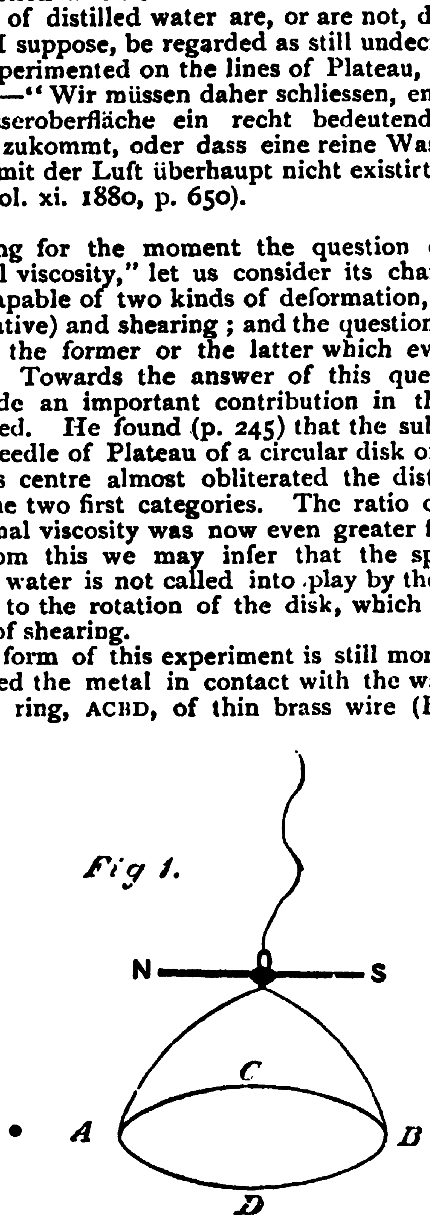

Fig 1.

supported by a fine silk fibre, so that it may turn freely about its centre. To give a definite set, and to facilitate forced displacements, a magnetized sewing needle, NS, is attached with the aid of wax. In order to make an experiment, the ring is adjusted to the surface of water contained in a shallow vessel. When all is at rest, the surface is dusted over with a little fine sulphur,[1] and the suspended system is suddenly set into rotation by an external

[5] *Nuovo Cimento*, vols. v.-vi., 1871-72, p. 260 (May 1872).

[1] Sulphur seems to be on the whole the best material, although it certainly communicates some impurity to the surface. Freshly heated pumice or wood-ashes sink immediately; and probably all powders really free from grease would behave in like manner.

magnet. The result is very distinct, and contrasts strongly with that observed by Plateau. Instead of the surface enclosed by the ring being carried round with it in its rotation, not the smallest movement can be perceived, except perhaps in the immediate neighbourhood of the wire itself. It is clear that an ordinary water surface does not appreciably resist shearing.

A very slight modification of the apparatus restores the similarity to that of Plateau. This consists merely in the addition to the ring of a material diameter of the same brass wire, CD (Fig. 2). If the experiment be repeated, the sulphur in-

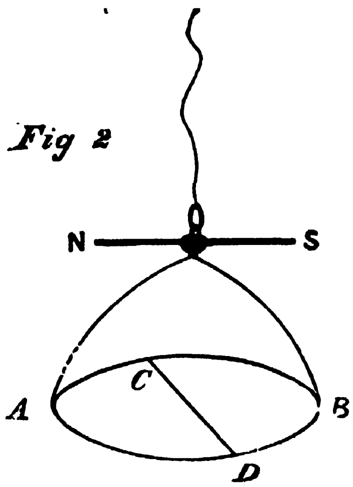

Fig 2

dicates that the whole water surface included within the semicircles now shares in the motion. In general terms the surface may be said to be carried round with the ring, although the motion is not that of a rigid body.

Experiments of this kind prove that what a water surface resists is not shearing, but local expansions and contractions of area, even under the condition that the total area shall remain unchanged. And this is precisely what should be expected, if the cause of the viscosity were a surface contamination. A shearing movement does not introduce any variation in the density of the contamination, and therefore does not bring Marangoni's principle into play. Under these circumstances there is no resistance.

It remains to consider liquids of the third category in Plateau's nomenclature. The addition of a little oleate of soda does not alter the behaviour of water, at least if the surface be tolerably fresh. On the other hand, a very small quantity of saponine suffices to render the surface almost rigid. In the experiment with the simple ring the whole interior surface is carried round as if rigidly attached. A similar effect is produced by gelatine, though in a less marked degree.

In the case of saponine, therefore, it must be fully admitted that there is a superficial viscosity not to be accounted for on Marangoni's principle by the tendency of contamination to spread itself uniformly. It seems not improbable that the pellicle formed upon the surface may have the properties of a solid, rather than of a liquid. However, this may be, the fact is certain that a contracting saponine surface has no definite tension alike in all directions. A sufficient proof is to be found in the well-known experiment in which a saponine bubble becomes wrinkled when the internal air is removed.

The quasi-solid pellicle on the surface of saponine would be of extreme thinness, and, even if it exist, could hardly be recognizable by ordinary methods of examination. It would moreover be capable of re-absorption into the body of liquid if unduly concentrated by contraction of surface, differing in this respect from the gross, and undoubtedly solid, pellicles which form on the surface of hard water on exposure to the atmosphere.

Two further observations relative to saponine may here find a place. The wrinkling of a bubble when the contained gas is exhausted occurs also in an atmosphere (of coal gas) from which oxygen and carbonic acid are excluded.

In Plateau's experiment a needle which is held stiffly upon the surface of a saponine solution is to a great extent released when the surface is contaminated by grease from the finger or by a minute drop of petroleum.

To return to the case of water, it is a question of the utmost importance to decide whether the superficial viscosity of even distilled water is, or is not, due to contamination with a film of foreign matter capable of lowering the tension. The experiments of Oberbeck would appear to render the former alternative very improbable; but, on the other hand, if the existence of the film be once admitted, the observed facts can be very readily explained. The question is thus reduced to this: Can we believe that the water surface in Plateau's apparatus is almost of necessity contaminated with a greasy film? The argument which originally weighed most with me in favour of the affirmative answer is derived from the experiments of Quincke upon mercury. It is known that, contrary to all analogy, a drop of water does not ordinarily spread upon the surface of mercury. This is certainly due to contamination with a greasy film; for Prof. Quincke (*Poggendorff's Annalen*, vol. cxxxix., 1870, p. 66) found that it was possible so to prepare mercury that water would spread upon it. But the precautions required are so elaborate that probably no one outside Prof. Quincke's laboratory has ever witnessed what must nevertheless be regarded as the normal behaviour of these two bodies in presence of one another. The bearing of this upon the question under discussion is obvious. If it be so difficult to obtain a mercury surface which shall stand one test of purity, why may it not be equally difficult to prepare a water surface competent to pass another?

The method by which I have succeeded in proving that Plateau's superficial viscosity is really due to contamination consists in the preparation of a pure surface exhibiting quite different phenomena; and it was suggested to me by an experiment of Mr. Aitken (*loc. cit.*, p. 69). This observer found that, if a gentle stream of air be directed vertically downwards upon the surface of water dusted over with fine powder, a place is cleared round the point of impact. It may be added that on the cessation of the wind the dust returns, showing that the tension of the bared spot exceeds that of the surrounding surface.

The apparatus, shown in Figs. 3 and 4, is constructed of sheet brass. The circular part, which may be called the *well*, has the dimensions given by Plateau. The diameter is 11 cm., and the depth 6 cm. The needle is 10 cm. long, 7 mm. in breadth at the centre, and about 0·3 mm. thick. It is suspended at a height of 2½ cm. above the bottom of the vessel. So far there is nothing special; but in connection with the well there is a rectangular trough, or tail-piece, about 2½ cm. broad and 20 cm. long. Between the two parts a sliding door may be inserted, by which the connection is cut off, and the circular periphery of the well completed. The action of the apparatus depends upon a stream of wind, supplied from an acoustic bellows, and discharged from a glass nozzle, in a direction slightly downwards, so as to strike the water surface in the tail-piece at a point a little beyond the door. The effect of the wind is to carry any greasy film towards the far end, and thus to purify the near end of the tail-piece. When the door is up, this effect influences also the water surface in the well upon which the jet does not operate directly. For, if the tension there be sensibly less than that of the neighbouring surface in the tail-piece, an outward flow is generated, and persists as long as the difference of tensions is sensible. The movements of the surface are easily watched if a little sulphur be dusted over; when the water in the well has been so far cleansed that but little further movement is visible, the experiment may be repeated without changing the water by contaminating the surface with a little grease from the finger or otherwise. In this way the surface may be freed from an insoluble contamination any number of times, the accumulation of impurity at the far end of the tail-piece not interfering with the cleanness of the surface in the well.

Another device that I have usually employed facilitates, or at any rate hastens, the cleansing process. When the operation is nearly complete, the movement of the surface becomes sluggish on account of the approximate balance of tensions. At this stage the movement may be revived, and the purification accelerated, by the application of heat to the bottom of the well at the part furthest removed from the tail-piece. It may, perhaps, be thought that convection currents might be substituted altogether for wind; but in my experience it is not so. Until a high degree of purity is attained, the operation of convection currents does not extend to the surface, being resisted by the film according to Marangoni's principle.

When the apparatus was designed, it was hoped that the door could be made a sufficiently good fit to prevent the return of the greasy film into the well; but experience showed that this could not be relied upon. It was thus necessary to maintain the wind during the whole time of observation. The door was, however, useful in intercepting mechanical disturbance.

A very large number of consistent observations have been recorded. The return of the needle, after deflection to 90°, is timed over an arc of 60°, viz. from 90° to 30°, and is assisted by a fixed steel magnet acting in aid of the earth's magnetism. A metronome, beating three times per second, facilitates the time measurement. As an example, I may quote some observations made on April 11.

The apparatus was rinsed and carefully filled with distilled water. In this state the time was 12 (beats). After blowing for a while there was a reduction to 10, and after another operation to 8. The assistance of convection currents was then appealed to, and the time fell to 6¾, and after another operation to 6. This appeared to be the limit. The door was then opened, and the wind stopped, with the result that the time rose again to 12. More water was then poured in until the needle was drowned to the depth of about half an inch. Under these conditions the time was 6¾.

It will be seen that, while upon the unprepared surface the time was nearly twice as great as in the interior, upon the purified surface the time was somewhat less than in the interior.

For the sake of comparison, precisely similar observations were made upon the same day with substitution for water of methylated alcohol. Before the operation of wind the time was 5; after wind, 5; on repetition, still 5. Nor with the aid of convection currents could any reduction be effected. When the needle was drowned, the time rose to 7¼. The alcohol thus presents, as Plateau found, a great contrast with the unprepared water; but comparatively little with the water after treatment by wind and heat.

An even more delicate test than the time of vibration is afforded by the behaviour of the surface of the liquid towards the advancing edge of the needle. In order to observe this, it is necessary to have recourse to motes, but all superfluity should be avoided. In a good light it is often possible to see a few motes without any special dusting over. In my experience, an unprepared water surface always behaves in the manner described by Plateau; that is, it takes part in rotation of the needle, almost from the first moment. Under the action of wind a progressive change is observed. After a time the motes do not begin their movement until the needle has described a considerable arc. At the last stages of purification, a mote, situated upon a radius distant 30° or 40° from the initial direction of the needle, retains its position almost until struck; behaving, in fact, exactly as Plateau describes for the case of alcohol. I fancied, however, that I could detect a slight difference between alcohol and water even in the best condition, in favour of the former. With a little experience it was easy to predict the "time" from observations upon motes; and it appeared that the last degrees of purification told more upon the behaviour of the motes than upon the time of describing the arc of 60°. It is possible, however, that a different range from that adopted might have proved more favourable in this respect.

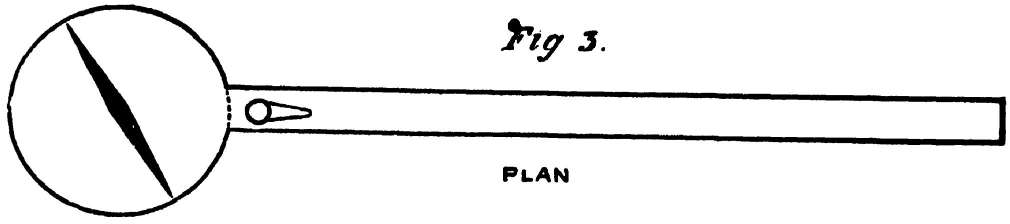

Fig 3.

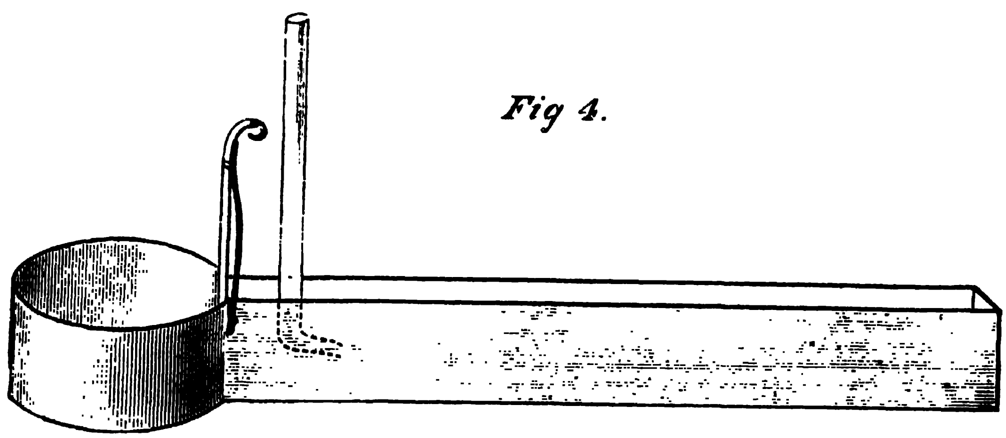

Fig 4.

The special difficulties under which Plateau experimented are well known, and appealed strongly to the sympathies of his fellow workers; but it is not necessary to refer to them in order to explain the fact that the water surfaces that he employed were invariably contaminated. Guided by a knowledge of the facts, I have several times endeavoured to obtain a clear surface without the aid of wind, but have never seen the time less than 10. More often it is 12, 13, or 14. It is difficult to decide upon the source of the contamination. If we suppose that the greasy matter is dissolved, or, at any rate, suspended in the body of the liquid in a fine state of subdivision, it is rather difficult to understand the comparative permanence of the cleansed surfaces. In the case of distilled water, the condition will usually remain without material change for several minutes. On the other hand, with tap water (from an open cistern), which I have often used, although there is no difficulty in getting a clean surface, there is usually a more rapid deterioration on standing. The progressive diminution of the tension of well-protected water surfaces observed by Quincke (*Poggendorff's Annalen*, vol. clx., 1877, p. 580) is most readily explained by the gradual formation of a greasy layer composed of matter supplied from the interior, and present only in minute quantity; although this view did not apparently commend itself to Quincke himself. If we reject the supposition that the greasy layer is evolved from the interior of the liquid, we must admit that the originally clean free surface, formed as the liquid issues from a tap, is practically certain to receive contamination from the solid bodies with which it comes into contact. The view, put forward hypothetically by Oberbeck, that contamination is almost instantly received from the atmosphere is inconsistent with the facts already mentioned.

Some further observations, made in the hope of elucidating this question, may here be recorded. First, as to the effect of soap, or rather oleate of soda. A surface of distilled water was prepared by wind and heat until the time was 5½, indicating a high degree of purity. The door being closed, so as to isolate the two parts of the surface, and the wind being maintained all the while, a few drops of solution of oleate were added to the water in the tail-piece. With the aid of gentle stirring, the oleate found its way, in a few minutes, under the door, and reached the surface of the water in the well. The time gradually rose to 13, 14, 15; and no subsequent treatment with wind and heat would reduce it again below 12. In this case there can be no doubt that the contamination comes from the interior, and is quickly renewed if necessary; not, however, so quickly that the tension is constant in spite of extension, or the surface would be free from superficial viscosity.

In like manner, the time upon the surface of camphorated dis-

tilled water could not be reduced below 10, and the behaviour of motes before the advancing needle was quite different from that observed upon a clean surface. A nearly saturated solution of chloride of sodium could not be freed from superficial viscosity; while, on the other hand, an addition of $\frac{1}{3}$ per cent. of alcohol did not modify the behaviour of distilled water.

The films of grease that may be made evident in Plateau's apparatus are attenuated in the highest degree. In a recent paper (*supra*, p. 364) I have estimated the thickness of films of olive oil competent to check the movements of camphor fragments as from one to two micro-millimetres; but these films are comparatively coarse. For example, there was never any difficulty in obtaining from tap-water surfaces upon which camphor was fully active without the aid of wind or special arrangements. I was naturally desirous of instituting a comparison between the quantities necessary to check camphor movements and the more minute ones which could be rendered manifest by Plateau's needle; but the problem is of no ordinary difficulty. A direct weighing of the contamination is out of the question, seeing that the quantity of oil required in the well of the apparatus, even to stop camphor, would be only $\frac{1}{64}$ milligram.

The method that I have employed depends upon the preparation of an ethereal solution of olive oil, with which clean platinum surfaces are contaminated. It may be applied in two ways. Either we may rely upon the composition of the solution to calculate the weight of oil remaining upon the platinum after evaporation of the solvent, or we may determine the relative quantities of solution required to produce the two sorts of effects. In the latter case we are independent of the precise composition of the solution, and more especially of the question whether the ether may be regarded as originally free from dissolved oil of an involatile character. In practice, both methods have been used.

The results were not quite so regular as had been hoped, the difficulty appearing to be that the oil left by evaporation upon platinum was not completely transferred to the water surface when the platinum was immersed, even although the operation was performed slowly, and repeated two or three times. On the other hand, there was no difficulty in cleansing a large surface of platinum by ignition in the flame of a spirit-lamp, so that it was absolutely without perceptible effect upon the movement of the needle over a purified water surface.

The first solution that was used contained 7 milligrams of oil in 50 c.c. of ether. The quantities of solution employed were reckoned in drops, taken under conditions favourable to uniformity, and of such dimensions that 100 drops measured 0·6 c.c. The following is an example of the results obtained:—On April 25, the apparatus was rinsed out and recharged with distilled water. Time = 13. After purification of surface by wind and heat, $5\frac{1}{2}$; rising, after a considerable interval, to 6. After insertion of a large plate of platinum, recently heated to redness, time unchanged. A narrow strip of platinum, upon which, after a previous ignition, three drops of the ethereal solution had been evaporated, was then immersed, with the result that the time was at once increased to $8\frac{1}{2}$. In subsequent trials, two drops never failed to produce a distinct effect. Special experiments, in which the standard ether was tested after evaporation upon platinum, showed that nearly the whole of the effect was due to the oil purposely dissolved.

The determination of the number of drops necessary to check the movements of camphor upon the same surface seemed to be subject to a greater irregularity. In some trials 20 drops sufficed; while in others 40 or 50 drops were barely enough. There seems to be no doubt that the oil is left in a rather unfavourable condition,[1] very different from that of the compact drop upon the small platinum surface of former experiments; and the appearance of the platinum on withdrawal from the water often indicates that it is still greasy. Under these circumstances it is clearly the smaller number that should be adopted; but we are safe in saying that $\frac{1}{15}$ of the oil required to check camphor produces a perceptible effect upon the time in Plateau's experiment, and still more upon the behaviour of the surface before the advancing needle, as tested by observation of motes. At this rate the thickness at which superficial viscosity becomes sensible in Plateau's apparatus is about $\frac{1}{10}$ of a micro-millimetre, or about $\frac{1}{6000}$ of the wave-length of yellow light.

[1] It should be stated that the evaporation of the ether, and of the dew which was often visible, was facilitated by the application of a gentle warmth.

A tolerably concordant result is obtained from a direct estimate of the smaller quantity of oil, combined with the former results for camphor, which were arrived at under more favourable conditions. The amount of oil in two drops of the solution is about 0·0017 milligram. This is the quantity which suffices to produce a visible effect upon the needle. On the large surface of water of the former experiments the oil required to check camphor was about 1 milligram. In order to allow for the difference in area, this must be reduced 64 times, or to 0·016 milligram. According to this estimate the ratio of thicknesses for the two classes of effects is about as 10 : 1.

Very similar results were obtained from experiments with an ethereal solution of double strength, one drop of which, evaporated as before, upon platinum, produced a distinct effect upon the time occupied by the needle in traversing the arc from 90° to 30°.

I had expected to find a higher ratio than these observations bring out between the thicknesses required for the two effects. The ratio 15 : 1 does not give any too much room for the surfaces of ordinary tap water, such as were used in the bath observations upon camphor, between the purified surfaces on the one side and those oiled surfaces upon the other, which do not permit the camphor movements.

It thus became of interest to inquire in what proportion the film originally present upon the water in the bath experiments requires to be concentrated in order to check the motion of camphor fragments. This information may be obtained, somewhat roughly it is true, by dusting over a patch of the water surface in the centre of the bath. When a weighed drop of oil is deposited in the patch, it drives the dust nearly to the edge, and the width of the annulus is a measure of the original impurity of the surface. When the deposited oil is about sufficient to check the camphor movements, we may infer that the original film bears to the camphor standard a ratio equal to that of the area of the annulus to the whole area of the bath. Observations of this kind indicated that a concentration of about six times would convert the original film into one upon which camphor would not freely rotate.

Another method by which this problem may be attacked depends upon the use of flexible solid boundary. This was made of thin sheet brass, and is deposited upon the bath in its expanded condition, so as to enclose a considerable area. Upon this surface camphor rotates, but the movement may be stopped by the approximation of the walls of the boundary. The results obtained by this method were of the same order of magnitude.

If these conclusions may be relied upon, it will follow that the initial film upon the water in the bath experiments is not a large multiple of that at which superficial viscosity tends to disappear. At the same time, the estimate of the total quantity of oil which must be placed upon a really pure surface in order to check the movements of camphor must be somewhat raised, say from 1·6 to 1·9 micro-millimetre. It must be remembered, however, that on account of the want of definiteness in the effects, these estimates are necessarily somewhat vague. By a modification of Plateau's apparatus, or even in the manner of taking the observations, such as would increase the extent of surface from which the film might be accumulated before the advancing edge of the needle, it would doubtless be possible to render evident still more minute contaminations than that estimated above at one-tenth of a micro-millimetre.

[P.S. *June* 4.—In order to interpret with safety the results obtained by Plateau, I thought it necessary to follow closely his experimental arrangements; but the leading features of the phenomenon may be well illustrated without any special apparatus. For this purpose, the needle of the former experiments may be mounted upon the surface of water contained to a depth of 1 or 2 inches in a large flat bath. Ordinary cleanliness being observed, the motes lying in the area swept over by the needle are found to behave much as described by Plateau. Moreover, the motion of the needle under the action of the magnet used to displace it is decidedly sluggish. In order to purify the surface, a hoop of thin sheet brass is placed in the bath, so as to isolate a part including the needle. The width of the hoop must, of course, exceed the depth of the water, and that to an extent sufficient to allow of manipulation without contact of the fingers with the water. If the hoop be deposited in its contracted state, and be then opened out, the surface contamination is diminished in the ratio of the areas. By this simple device there is no difficulty in obtaining a highly purified surface, upon which motes lie quiescent, almost until struck by the oscillating needle. In

agreement with what has been stated above, an expansion of three or four times usually sufficed to convert the ordinary water surface into one upon which superficial viscosity was tending to disappear.

I propose to make determinations of the actual tension of surfaces contaminated to various degrees; but in the meantime it is evident that the higher degrees of purity do not imply much change of tension. In the last experiment, upon a tolerably pure surface, if we cause the needle to oscillate rapidly backwards and forwards through a somewhat large angle, we can clear away the contamination from a certain area. This contamination will, of course, tend to return, but observation of motes shows that the process is a rather slow one.

The smallness of the forces at work must be the explanation of the failure to clean the surface in Plateau's apparatus by mere expansion. For this experiment the end wall was removed from the tail-piece (Fig. 3), and a large flexible hoop substituted. By this means, it was hoped that when the whole was placed in the bath it would be possible, by mere expansion of the hoop, to obtain a clean surface in the well. The event proved, however, that the purification did not proceed readily beyond the earlier stages, unless the passage of the contamination through the long channel of the tail-piece was facilitated by wind.]

UTILIZATION OF NIAGARA FALLS.

A SYNDICATE in the United States have acquired a considerable area of land on the American side of the Niagara River, at some distance above the great Falls. They propose to use it for mill sites, and to supply the mills with power by utilizing a small fraction of the water-power which is available on the Falls. The actual fall of level at Niagara is about 200 feet. Suppose that about 4 per cent. of the water going over the Falls is taken, and an effective fall of 140 feet, irrespective of losses in the tail race, obtained, there might be utilized 120,000 horsepower. It is proposed to take the water by a short lateral canal, to allow it to descend vertically in shafts in which turbines will be placed, and then to discharge it by a tunnel tail race passing beneath the present town of Niagara, at a point below the Falls. It is part of the plan to transmit a portion of the power to the important manufacturing town of Buffalo, eighteen miles distant.

The project involves problems of very great complexity. The hydraulic motors will be of a size not hitherto constructed, and the governing conditions are different from those commonly met with where water power is utilized on streams of variable and limited flow. Then in the distribution of the power further problems arise. Power can be distributed to great distances by Hirn's system of wire ropes, as at Schaffhausen; by water or air under pressure, as in the compressed air systems of Paris and Birmingham and the Hydraulic Power Company's system in London. In Switzerland and America progress has been made in distributing large power to great distances electrically. The choice amongst such methods of those which are most economical and most likely to suit the wants of mill-owners, requires very careful consideration.

Hence the Cataract Company have resolved to invite from certain selected engineers and engineering firms, plans for the utilization at Niagara of 120,000 horsepower, and to submit the plans for an authoritative opinion to the judgment of a Scientific International Commission. The Commission will consist of Sir William Thomson, F.R.S., as President; Prof. Mascart, Member of the Institut, and Director of the Bureau Central Météorologique, Paris; Colonel Theodore Turrettini, who was director of the works of the Saint Gothard Tunnel, and is director of the works for the utilization of the motive power of the Rhone at Geneva; and, lastly, Dr. Coleman Sellers, formerly of the firm of Messrs. Sellers and Co., of Philadelphia, and now Professor of Engineering at the Stevens Institute, Hoboken, and at the Franklin Institute of Pennsylvania. Prof. W. C. Unwin, F.R.S., is the Secretary to the Commission.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, June 19.—Prof. Charles Stewart, President, in the chair.—Mr. W. H. Beeby exhibited a specimen of *Rumex propinquus* new to Britain, and procured in Shetland.—Mr. Thomas Christy exhibited and made remarks upon a specimen of *Callistemon rigidum*.—Mr. E. M. Holmes exhibited some marine Algæ new to Britain, including *Ascocyclus reptans*, *Halothrix lumbricalis*, *Harveyella mirabilis*, *Sorocarpus uvæformis*, and *Vaucheria litorea*; also specimens of *Rhodymenia palmata* with antheridia, and *Punctaria tenuissima* in fructification, the last two not having been previously recorded to occur in this state in Great Britain.—The following papers were then read:—Observations on the protection of buds in the tropics, by M. C. Potter.—On the distribution of the South American Bell-birds belonging to the genus *Chasmorhynchus*, by J. E. Harting.—On the vertical distribution of plants in the Caucasus, by Dr. Gustav Radde.—Notes on the *Forficulidæ*, with descriptions of new genera and species, by W. F. Kirby.—This meeting terminated the Session of 1889–90.

Entomological Society, July 2.—Prof. J. O. Westwood, Hon. Life-President, in the chair.—Lord Walsingham exhibited some rare Micro-Lepidoptera collected by himself at Cannes, including *Eudemis helichrysana*, *Conchylis rubricana*, Millière; a new *Depressaria* from *Opoponax cheironium*, which is about to be described by M. A. Constant, and *Bucculatrix helichrysella*; and also a volume of drawings of larvæ of the genus *Eupithecia*, by Mr. Buckler, which formerly belonged to the late Rev. H. Harpur Crewe.—Mr. McLachlan exhibited larvæ and cocoons of *Mecyna deprivalis*, Walk., sent by Mr. W. W. Smith, of Ashburton, New Zealand; the species feeds commonly on *Genista capensis*, an introduced plant.—Mr. S. Stevens, in speaking of a tour which he had lately made in Devonshire, remarked on the extreme scarcity of insects on the coast of that county as compared with the coasts of Kent and Sussex; there were very few larvæ, and the vegetation was very luxuriant and very little eaten: he thought it possible that the reason of the scarcity was the heavy rainfall of South Devon, which washed off and destroyed the young larvæ. Mr. Barrett said that his experience had been the same, and that he put it down to the violence of the winds which beat the insects from the trees. Mr. Blandford remarked that he had found Coleoptera abundant on the Braunton Burrows, near Barnstaple, but very scarce in other localities. Mr. Mason and others took part in the discussion which followed.—Prof. Westwood read a paper on a species of Aphis affecting the bread-fruit tree, which he had named *Siphonophora artocarpi*: at the conclusion of his paper he alluded to the use of Paris-green as a destructive agent for insects. Mr. Blandford then made some remarks as to the use of London-purple (another arsenic compound) as an insecticide in the place of Paris-green; he stated that the compound was a waste product, and one-tenth the cost of Paris-green, and further that it was more soluble and more easily applied; he was also of opinion that arsenic compounds do not greatly affect sucking insects, such as Aphides, the ordinary kerosene preparations being more suitable for their destruction. Several Fellows took part in the discussion that followed.

EDINBURGH.

Royal Society, June 16.—The Hon. Lord M'Laren, V.P., in the chair.—A list of West Australian birds, showing their geographical distribution throughout Australia, by Mr. A. J. Campbell, Melbourne, was communicated.—Dr. Buchan discussed a difference between the diurnal barometric curves at Greenwich and at Kew.—Dr. Sang communicated a paper on the general formulæ for the passage of light through a spherically arranged atmosphere.—Dr. Buchan gave an account of a remarkable barometric reading at the Ben Nevis Observatory on April 8, 1890.—Prof. Crum Brown read the third part of a paper, written by himself in conjunction with Dr. James Walker, on synthesis by means of electrolysis.

July 7.—Sir William Thomson, President, in the chair.—The Victoria Jubilee Prize for 1887–90 was presented to Prof. Tait for his work in connection with the *Challenger* Expedition and his other researches in physical science. The Keith Prize for 1887–89 was presented to Prof. Letts for his researches into the organic compounds of phosphorus. The Neill Prize for 1886–89 was awarded to Mr. Robert Kidston for his researches in fossil botany.—Sir W. Thomson read a paper on the submarine cable problem, with electromagnetic induction. The solution of the problem with intermittent or alternating currents of period so long that the distribution of current over a given cross-section of the core is uniform, is already well known. Sir W. Thomson extends the solution, through all intermediate stages, to the

case in which the period is so short that the current is confined to an exceedingly thin surface-layer of the core. He has worked out the conditions which obtain with a core and sheath of any forms. The thickness of the layer depends only, other things being equal, upon the period of alternation—the law being that given by Fourier for the penetration of the annual and diurnal heat-waves into the earth's crust. The distribution of density throughout the layer depends upon the form and relative position of the core and the sheath.—Prof. Crum Brown and Dr. James Walker, in continuation of their research on the formation of dibasic acids by electrolysis, communicated a paper on the synthesis of suberic acid and a new acid $(CH_2)_{12}(COOH)_2$.—Prof. Tait exhibited some graphic records of impact, obtained by the method described in a previous paper.—Dr. James Geikie read a paper by Mr. R. Kidston, on the fossil flora of the Potteries coal-field.—The Hon. Lord M'Laren read a paper on the reduction of certain algebraic equations.—Prof. Tait read an account, by Prof. A. C. Mitchell, of a preliminary experiment on the thermal conductivity of aluminium, which he makes out to be almost exactly equal to that of the best copper.—Dr. Ralph Stockman and Mr. D. B. Dott communicated a paper on the pharmacology of morphine and its derivatives.—Dr. W. Somerville made a communication on *Larix europæa* as a breeding-place for *Hylesinus piniperda*.

PARIS.

Academy of Sciences, July 7.—M. Hermite in the chair.—Photographic stellar spectra obtained by MM. Henry at Paris Observatory, by Admiral Mouchez. (See Our Astronomical Column.)—On the oxidation of the sulphur of organic compounds, by MM. Berthelot, André, and Matignon. The authors give a general method for the estimation of sulphur in all organic bodies containing that element, consisting in burning the body either alone or mixed with camphor in an atmosphere of compressed oxygen in the presence of about 10 c.c. of water, with subsequent precipitation of the sulphuric acid in the usual manner.—Heats of combustion of some sulphur compounds, by MM. Berthelot and Matignon.—Heats of combustion of erythrite, arabinose, xylose, raffinose, and inosite, by MM. Berthelot and Matignon.—New experiments on the silent discharge, by M. P. Schutzenberger.—The active elasticity of muscle, and the energy used in its creation in the case of static contraction, by M. A. Chauveau.—Note on the difficulty in recognizing the Cysticerca of *Tænia saginata* or *inermis* in the muscles of the calf and cow, by M. A. Laboulbène.—On the propagation of sound in cylindrical tubes, by M. V. Neyreneuf.—The theory of periodic comets, by M. O. Callandreau. The author finds that the "capture" theory of periodic comets is sufficient to explain the characteristic properties of their orbits and the objections that have been opposed to it.—On a photograph of the ring nebula in Lyra obtained at Bordeaux Observatory, by M. G. Rayet. (See Our Astronomical Column.)—Partial eclipse of the sun of June 17, by M. J. Léotard. The times of first and last contact are given.—Occultation of the double star β Scorpii by the moon on June 29, by the same author.—On the anomalous propagation of waves, by M. Gouy.—Action in the dry way of different arsenates of potassium and sodium on the sesquioxides of some metals, by M. C. Lefèvre.—On a new method of preparing basic nitrate of copper and some crystallized subnitrates, by M. G. Rousseau. The basic nitrates are obtained in large crystals from the hydrates of corresponding neutral salts.—On double bromides of phosphorus and iridium, by M. G. Geisenheimer.—On some chromoiodates, by M. A. Berg.—The artificial production of boracite in the wet way, by M. A. de Gramont.—On the nitroprussides, by M. Prud'homme.—On the cause of the alteration which certain compounds of the aromatic series undergo under the influence of air and light, by M. André Bidet.—Transformation of glucose into sorbite, by M. J. Meunier.—On the hydrogenation of sorbine and the oxidation of sorbite, by MM. Camille Vincent and Delachanal.—Syntheses by means of cyanacetic ether: dicyanacetic ethers, by M. A. Haller.—The preparation of certain ethers by means of fermentation, by M. Georges Jacquemin.—On the physiological action of thallium salts, by Mr. J. Blake.—On the pretended circulatory system and genital organs of Neomenidæ, by M. G. Pruvot.—On the *rôle* of the bud-shaped pedicles of sea-urchins, by M. Henri Prouho.—On the histological constitution of some Nematoids of the order Ascaris, by M. Léon Jammes.—On the comparative physiology of the sense of smell, by M. Raphael Dubois.—The basaltic eruptions of the valley of the Allier, by M. Marcellin Boule.—On the mineralogical composition of the volcanic rocks of the islands of Martinique and Saba, by M. A. Lacroix.—On the relation between joints and some surface wrinklings near Doullens, by M. Henri Lasne.

BERLIN.

Physical Society, June 27.—Prof. von Helmholtz, President, in the chair.—Dr. Dubois spoke on magnetic closed circuits, whose theory constitutes, in addition to hysteresis, the most important advance which magnetism has made in recent times. He gave a short historical review of the more important published works on the subject, pointing out that they were at first the result rather of an endeavour to make the requisite calculations connected with dynamos for technical purposes, and had only attracted the attention of physicists in a secondary and subordinate degree. The works of Faraday, Maxwell, Sir W. Thomson, Hopkinson, Lord Rayleigh, and the experimental researches of Rowland, were briefly mentioned; Hopkinson's formulæ and Lord Rayleigh's graphic representations were then more fully treated; and, finally, the formula for the magnetization of a closed circuit was developed.—Dr. Raps described an arrangement of Topler's mercurial air-pump, by means of which he had made it work automatically; he further described a compensated air-thermometer which he had constructed, and exhibited both instruments to the Society.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The International Annual of Authony's Photographic Bulletin, vol. 3, 1890–91 (Iliffe).—Reflections on the Motive Power of Heat: N. L. S. Carnot; edited by R. H. Thurston (Macmillan and Co.).—Hypnotism: A. Moll (W. Scott).—Light: E. W. Tarn (Lockwood).—Elementary Mechanics (Blackie).—Timbers, and How to Know Them: Dr. R. Hartig; translated by W. Somerville (Edinburgh, Douglas).—Introduction to Fresh-water Algæ: Dr. M. C Cooke (K. Paul).—Short Logarithmic and other Tables, 4th edition: W. C. Unwin (Spon).—Walks in the Ardennes, new edition: P. Lindley (London).—Tourist Guide to the Continent: P. Lindley (London).—Sectional Map of South Dakota (Chicago, Rand).—Pocket Map, &c., of Michigan (Chicago. Rand).—Confidential Chats with Mothers: Mrs. Bowdick (Baillière).—British Cage Birds, Part 3: R. L. Wallace (L. Gill).—Canary Book, Part 3: R. L. Wallace (L. Gill).—Mathematical and Physical Papers, vol. 3: Sir Wm. Thomson (Cambridge University Press).—Electric Light Fitting: J. W. Urquhart (Lockwood).—Catalogue of the Fossil Reptilia and Amphibia in the British Museum (Natural History), Part 4: R. Lydekker (London).—L'Esprit de Nos Bêtes: E. Alix (Paris, J. B. THURSDAY, JULY 24, 1890.

THE COLOURS OF ANIMALS.

The Colours of Animals: their Meaning and Use especially considered in the case of Insects. By Edward Bagnall Poulton, M.A., F.R.S., &c. With Chromolithograph Frontispiece and Sixty-six Figures in Text. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1890.)

THIS new volume of the International Scientific Series gives an excellent summary of the most recent researches as to the varied uses of the colours of animals, and more especially of those admirable observations and experiments on variable protective colouring with which Mr. Poulton's name is associated, and which mark an era in this branch of natural history. The main outlines of the subject are so well known, both to naturalists and to general readers, that it will only be necessary here to indicate some of the more important of the matters now first treated in a popular work, and to make a few remarks on some of the more difficult problems discussed in the volume.

The first chapter gives a short but very clear statement of the physical cause of animal colours, and contains some valuable observations on the effect of thin films of air or of liquids in the production of iridescent colours. In some cases dried insects lose some of their metallic colours, but these reappear when the specimen is dipped in water. Even living beetles have been observed to lose their lustre after hybernation, and to regain it after drinking water. Then we have a sketch of the general uses of colour to animals, and it is shown that the frequent dark colour of arctic insects has probably a physiological use in enabling them to absorb as much heat as possible during the brief period of their existence under an arctic sun. This is supported by some direct observations; but the further suggestion that the white colour of so many arctic birds and mammals has also a physiological use in checking the loss of heat through radiation is less satisfactory. Not only is there no evidence to show that the loss of animal heat is at all influenced by the colour of the fur or feathers, but it is evident that the same result could be brought about by a very slight increase in the texture or thickness of the covering, such as actually occurs in all arctic animals. In the seventh chapter there is a very interesting discussion on the way in which the white winter coat of arctic animals is produced, and it is shown that in the American arctic hare the brown hairs of the summer coat turn white at the tips, while a quantity of new white hairs grow among them, producing at once the thickening of the coat for warmth and the change of colour for protection. That this last is the only function of the colour is well indicated by the case of the raven, which is found in the extreme north of the polar regions, even during the most intense colds of winter, wherever the reindeer and musk-sheep range. Yet it is here as black as elsewhere, although the occasional occurrence of pied and even of white ravens in various parts of Europe and America shows that a white race could be produced if that colour was of any advantage to the bird in its arctic habitat.

Two chapters are devoted to a subject which Mr. Poulton has made especially his own, the variable protective colouring of insects. This was first noticed by the late Mr. T. W. Wood, the well-known natural history artist who furnished many of the best illustrations for Darwin's "Expression of the Emotions in Man and Animals," and the result of his experiments were brought before the Entomological Society of London in 1867. Since then a few other observations have been made by several naturalists, but little was known of the extent or of the exact causes of the adaptation till Mr. Poulton carried out his experiments for several years in succession, and on so extensive a scale that in one year over 700 larvæ of the small tortoiseshell butterfly (*Vanessa urticæ*) were observed under various surroundings, and the colours of the resulting chrysalides recorded. In this way pupæ were obtained varying from black to nearly white or metallic golden colours, in each case corresponding more or less closely to the coloured surfaces on which they were suspended. By changing the coloured surroundings at different stages of the process, and by blinding some of the larvæ, it was ascertained that the period of susceptibility is the quiescent stage just before the change to the pupa state, and that in this case vision has nothing to do with the change of colour. By a number of ingenious experiments, it was ascertained that the whole surface of the skin is sensitive to the action of variously-coloured light, and the effect on the pupa-skin is produced, not directly, as by some photographic action, but by a physiological process acting through the nervous system. In some cases even the cocoons spun by the larvæ are modified by the surrounding colours; and still more curious changes are effected in the larva itself when, as in so many cases, the same species feeds on several plants having differently-coloured leaves. Even the presence of numerous dark twigs has been shown to cause a corresponding change of colour in the larva of the peppered moth (*Amphidasis betularia*). These two chapters afford a beautiful example of a very difficult and interesting inquiry leading to an explanation of some of the most curious colour-phenomena in the animal kingdom. Mr. Poulton points out the essential difference between this mode of colour-adjustment and that of the chameleon, and of some crustacea, frogs, and fishes, which can rapidly adjust their colours to new surroundings, in the following passage:—

"The essential difference between the two kinds of adjustment is that, in the one case, the pigmented part of certain cells contracts in obedience to nervous stimuli, and thus alters the general appearance; while in the other case the coloured part is actually built up of the appropriate tint, or loses its colour altogether and becomes transparent in obedience to the same stimuli. The frog or fish has a series of ready-made screens which can be shifted to suit the environment; the insect has the power of building up an appropriate screen. In many cases, however, the green colour of caterpillars is due to the ready-made colour of the blood, which becomes effective when pigment is removed from the superficial cells, but which disappears when the latter are rendered opaque. Here, however, the superficial cells form the screen which has to be built up, or from which the colour must be dismissed; and in certain species

even the colour of the blood is entirely changed in the passage from a green to a dark variety, or *vice versâ*. Hence it is to be expected that the changes occurring in an insect will occupy a considerable time as compared with those which take place in a frog. Another difference between the two processes is that the stimulus from the environment falls upon the eye in the one case, and probably upon the surface of the skin in the other."

Mr. Poulton's work is of special importance for the numerous experimental proofs he gives of the protective value of many of the peculiarities in the colour markings or attitudes of insects. Thus the green lizard (*Lacerta viridis*) generally failed to detect a "stick caterpillar" in its position of rest, although the insect is seized and greedily devoured directly it moves. The value of the tufts of hair, called "tussocks," on many caterpillars was also proved experimentally.

"A caterpillar of the common vapourer moth (*Orgyia antiqua*) was introduced into a lizards' cage, and when attacked, instantly assumed the defensive attitude, with the head tucked in and the 'tussocks' separated and rendered as prominent as possible. An unwary lizard, seized the apparently convenient projection; most of the 'tussock' came out in its mouth, and the caterpillar was not troubled further. The lizard spent a long and evidently most uncomfortable time in trying to get rid of its mouthful of hairs."

There is a most excellent account of the larva of the lobster moth (*Stauropus fagi*) which is protected by its marvellous resemblance to a withered beech-leaf and its stipules, and is also able to assume a terrifying attitude, when it resembles some large and strangely formed spider. When one of these larvæ had assumed the terrifying attitude, a marmoset monkey was much impressed by the alarming sight, and only ventured to attack after the most careful examination, and even then in the most cautious manner. A lizard exhibited the same caution before the larva was attacked. The same insect is also to some extent protected from ichneumons by two black marks, exhibited only when attacked, which resemble those produced by the stings of ichneumons, and thus prevent an attack, since these parasites always avoid larvæ which are already occupied.

Two chapters are devoted to an excellent account of the various forms of mimicry, a subject which, however interesting, has been so often treated that there is comparatively little new to be said upon it; and then we have two chapters on sexual colours, which will offer material for a few remarks, as the whole subject is full of difficulties, and requires much more observation and experiment before the problems it presents, can be satisfactorily settled.

Mr. Poulton fully accepts Darwin's theory of female choice as the source of the greater part of the brilliant colour, delicate patterns, and ornamental appendages that exist among animals, and especially among birds and insects. Much stress is laid on the observations of two American writers on the courtship of spiders. These show that spiders resemble birds in the strange postures and long-continued antics of the male during courtship, and that he always exhibits whatever portion of his body is most conspicuously coloured.

"The female always watches the antics of the male intently, but often refuses him in the end, 'even after dancing before her for a long time.' Such observations strongly point towards the existence of female preference based on æsthetic considerations."

To the last four words we demur, as being altogether unproved. Why *æsthetic* considerations? Why not a deficiency in activity, or in size, or in some exciting odour, or in the excitability of the female at the moment? Any of these causes, or others unknown to us, may determine the acceptance or rejection of a male spider; and it is to be noted that the long-continued and careful observations of these American authors have not enabled them to adduce a single case in which any deficiency of colour was observed in a rejected male. There is, indeed, one case in which two well-marked male varieties of a species exist—one red, the other black; and these assume different attitudes in courtship. Messrs. Peckham say: "the *niger* form, evidently a later development, is much the more lively of the two, and whenever the two varieties were seen to compete for a female, the black one was successful." On this Mr. Poulton remarks: "It must be admitted that these facts afford the *strongest support* to the theory of sexual selection"; but there is not a particle of proof that the black colour was the cause of the selection rather than the "superior liveliness" which all breeders of animals believe to be the most attractive characteristic a male can possess.

Mr. Poulton speaks continually of the possession of an "æsthetic sense by those creatures in which sexual ornament occurs, but no proof whatever of this is given, other than the fact that insects do recognize diversities of colour, and that a few birds collect bright objects, as in the case of the bower-birds. This habit, existing in a few species only of one of the highest groups of birds, can hardly be held to be a proof that in all birds, even in such comparatively low types as ducks and Gallinaceæ, slight variations of colour in the male determine the choice of the female.

This æsthetic sense is supposed to exist even in insects, and some very doubtful facts are alleged in support of this view. It is stated that if all the brightly-coloured butterflies and moths in England were arranged in two divisions, the one containing all the beautiful patterns and combinations of colours, the other including the staring, strongly-contrasted colours and crude patterns, we should find that the latter would contain, with hardly an exception, the species in which independent evidence has shown, or is likely to show, the existence of some unpleasant quality. The former division would contain the colours displayed in courtship and when the insect is on the alert. And it is added that there is an immense difference between the two divisions—the one most pleasing, the other highly repugnant, to our æsthetic sensibilities, because the pleasing colours have been determined by the insect's sense of what is *beautiful*, the displeasing colours by the need for what is *conspicuous* to a vertebrate enemy. If there is, indeed, any such great and constant difference due to these causes, it must exist in all countries, and in all groups where these causes have come into play; but it is very doubtful whether any such difference does exist. In looking over a general collection of butterflies few would decide that the Danaidæ, Acræidæ, and Heliconidæ showed any deficiency in beauty and harmony of colour; yet they are pre-

eminently the groups in which warning colours are predominant. So, also, the American and Eastern sections of the genus Papilio which are both subjects of mimicry and have all the other characteristics of protected groups with warning colours, are all exquisitely beautiful, with their rich green or crimson spots on a velvety black ground. And if we turn to birds, in which, as there are no known warning colours, all that are not protective are supposed to be due to sexual selection, we find, among much that is beautiful, great numbers of the harshest contrasts and most inharmonious combinations of colour that it is possible to conceive. Such are the blues and yellows and reds of the macaws and of a great number of other parrots; the equally harsh colours of the barbets and the toucans; the contrasted blue and purple or magenta and black of many of the chatterers. In many of these, no doubt, the texture of the surface is so delicate and the colours so bright and pure that we cannot but admire the tints themselves, although it is impossible to claim for the mode in which they are combined even the rudiments of æsthetic beauty. On the other hand, we find really beautiful combinations of colour and marking where sexual selection has certainly not come into play. Such are the exquisite tints and patterns of the cones, cowries, olives, harps, volutes, pectens, and innumerable other molluscan shells; while many of the sea-anemones, and considerable numbers of the caterpillars with warning colours, are equally beautiful.

Still more doubtful and more opposed to reasonable probability is the statement that "our standards of beauty are largely derived from the contemplation of the numerous examples around us, which, strange as it may seem, have been created by the æsthetic preferences of the insect world"—alluding, of course, to the colours and structures of flowers as being due to the need of attracting insects to fertilize them. Here objection may be taken, first, to the term *preferences* as applying to mere beauty in the flower, and still more emphatically to the term *æsthetic*, which there is not a particle of evidence for believing to enter at all into an insect's very limited mentality. Insects visit flowers wholly and solely, so far as we know, to obtain food or other necessaries of their existence, and every fact connected with the colours of flowers can be explained as due to the advantage of conspicuousness amid surrounding foliage, and distinctness from other flowers which are especially suited to different species of insects. When cows and horses refuse to eat the acrid buttercup, we do not say that the glaring yellow colour is repugnant to their æsthetic sensibilities, and that their dislike to the plant as food is the result; yet this would be less improbable than that bees and butterflies have any admiration of or liking for flowers independent of the supply of their physical wants. Moreover, a large part of the beauty *we* see in flowers is independent of colour, and is due to the graceful forms of individual flowers, their elegant groupings, and their charming contrast to the foliage which surrounds them. We now know that much of the variety in the form and position of flowers is dependent on their own physical needs, the protection of the pollen and the germ from rain, wind, or insect enemies, and that it has been produced by natural selection acting under the limitations due to the fundamental laws of vegetable growth. The purity and intensity of the colours are due to the fact that such colours offer a greater contrast to the ever-varying tints of foliage, twig, and bark, seen under constant modifications of light and shade, than would be offered by more sober hues; and thus it is that flowers usually exhibit the purest and brightest colours, which, combined with their elegant or curious forms, and the exquisite setting of green foliage which surrounds them, produce a general effect which is to us inexpressibly charming. But we have no reason to believe that any of the lower animals are affected in the smallest degree by these truly æsthetic feelings, and the use of the term as applied to them is simply begging the question, and is, therefore, not scientific.

It is because Mr. Poulton himself admits that the theory of sexual selection is still to some extent *sub judice* that the preceding remarks have been made in the way of protest against the use of terms which themselves tend to prejudge the case. In his chapters on this subject he has brought many arguments in its favour, some of which are ingenious and novel; but they all appear to rest on very slender evidence or to admit of another interpretation. They will, however, be useful as an incitement to further observation on this most interesting question, which, in all probability, will not be finally settled by the present generation of naturalists.

The book is well illustrated by numerous excellent woodcuts and a coloured plate, and there appear to be few if any misprints, the only one calling for remark being the placing of the cut at p. 34 upside down, so that the resemblance to a catkin is lost. Mr. Poulton is to be congratulated on having produced so readable and suggestive a volume on one of the most attractive departments of natural history, and on having by his own researches contributed so largely to the solution of some of the more interesting problems which it presents.

ALFRED R. WALLACE.

A HAND-BOOK OF ASTRONOMY.

Hand-book of Astronomy. Parts II. and III. By George F. Chambers, F.R.A.S. (Oxford: Clarendon Press, 1890.)

IN commenting upon the first part of this revised edition of Mr. Chambers's "Descriptive and Practical Astronomy," we pointed out the utter insufficiency of the portion devoted to the study of the sun, inasmuch as it left solar spectroscopy altogether out of consideration. Such an arrangement is a breach in the continuity of scientific inquiry, and a grievous fault in a hand-book that makes some pretence to give facts in historical sequence.

The second volume deals with instrumental and practical astronomy, and in it we find spectroscopical astronomy interpolated; the work that has been done in this direction following the description of the instruments employed. This circumstance, however, at once exhibits an inconsistency, for, if spectroscopy properly follows a description of the spectroscope, then telescopy should follow a description of the telescope; whereas in the former volume the aspects of the heavenly bodies were described, and in this the instruments by means of which they are observed.

A cause for the omission of all spectroscopic information from the sections to which it respectively and properly belongs, and its relegation to a couple of chapters in another volume, would be difficult to find. To these chapters, however, for which Mr. Maunder, of Greenwich Observatory, is made responsible, all matters spectroscopical have been referred, and so far as space permitted, Mr. Maunder has furnished a very comprehensive summary of the subject he had in hand; hence it may be that Mr. Chambers has acted wisely in intrusting the discussion of spectroscopic labours to a practical man. But the first duty of the compiler of such a volume as the one before us is to chronicle facts without comment or bias, and to lay before his readers the conclusions that have been drawn from them, leaving them to stand or fall on their own merits. This, however, has not been done; many observations are introduced with disparaging remarks, and conclusions deduced from them are said to be "most ingenious, but far from satisfying," without any evidence being adduced of their fallacy.

We also note that the sequence of spectra observed in comets as they approach to or recede from the sun, and supporting the meteoritic origin of these bodies, is mildly objected to. The shift in the position of the citron comet band, which admits of a ready explanation when the masking effect of the first flutings of manganese and lead is considered, is questioned, and the sequence is said to be

"partly founded on discrepancies as to the positions of some of the bands, which may prove to be significant but which, more probably, are simply due to the difficulties of observation, and partly to the fact that the yellow band of the carbon series in cometary spectra does not always show the same exact correspondence with the carbon band as do those in the green and blue. In particular, it shows at times two or more maxima within its borders, and its redward edge is rather diffused. The positions of these maxima are variously given, but appear to be about 5570 and 5450. There are not a few instances, also, in which this yellow, or, rather, citron, band has been recorded as having its sole maximum at one or other of these wave-lengths. Lockyer ascribes these divergences to the influence of the flutings of manganese and lead, but, bearing in mind the great difficulty of many of these observations, and that the citron band is much the faintest of the three, it seems scarcely safe at present to draw such an inference."

It is here acknowledged that the citron comet band has not a fixed position in the spectrum, and that its appearance is not always the same. Whether it is safe to conclude that the two maxima at λ 557 and λ 545 are due respectively to the flutings of manganese (558) and lead (546), it is not now our place to discuss. Since, however, the shift is real, it is hardly scientific to assert that the measures of its wave-length given by various observers are discrepancies of observation. Again, it is to be regretted that in the survey of cometary spectra no mention is made of Dr. Huggins's important observations in 1866-67 of "a bright line between *b* and F, about the position of the double line of the spectrum of nitrogen," in the spectrum of each of two small comets that appeared in those years. This is also the position of the chief line in the spectrum of the nebulæ, and suggests the connection that exists between the two bodies.

The standard of excellence deemed necessary to establish a sequence in the spectra of comets, as they approach to or recede from the sun, has not been applied all through the work. We find a table showing in parallel columns the 'general agreement between the motions of stars in line of sight as measured by Dr. Huggins, Mr. Maunder, and at Rugby. To one unacquainted with instrumental difficulties, the motion of stars in line of sight would appear to be a quantity that may be determined with some accuracy; but to those who know the pitfalls, by far the greater number of such observations appear worthless, for the accuracy attained in the majority of measurements is not sufficiently fine to allow any reliance to be placed upon them. In many cases a star, according to observation, has been moving towards the earth at the rate of about 50 miles a second, whilst another observation, made, perhaps, two minutes afterwards, indicated that it was receding from the earth with the same velocity. It is hardly just, therefore, to select certain determinations and arrange them in parallel columns to demonstrate the efficiency of the method adopted. At the end of the discussion of these motions, a note occurs on Algol. It is shown that the satellite theory of this star's variability, propounded by Goodricke and developed by Pickering, is supported by the fact that observations of its motion in line of sight, may be divided into groups, which indicate that at one time it is approaching our system, and at another receding from it owing to its orbital velocity. With these results we have nothing to do; but, if we remember rightly, Prof. Vogel was the first to demonstrate the periodic shift of the F line towards the red and the violet end of the spectrum, and in a communication to the Berlin Academy he gave the elements of the orbit traversed. This being so, it is curious to find that Prof. Vogel's discussion of his photographs has been omitted, although some months intervened between the communication and the publication of this volume, whilst Mr. Maunder's later division of his grievously discrepant observations into groups has been included.

There are a few other points to which we would call the author's attention. In the portion devoted to chronological astronomy, the dates of the commencement of the seasons and their consequent lengths, are given for 1860, the corresponding dates for 1890 being inserted in a footnote. It would have cost but little trouble to substitute the latter times when bringing the book up to date, and no purpose is served by the present arrangement.

A new feature, and one to be commended, is the insertion of plans and specifications for small observatories; this will doubtless be appreciated by amateur astronomers, since the directions and measurements which accompany them are supposed to be such that any builder of ordinary intelligence will be enabled to undertake the construction. It was hardly necessary, however, to give the description and sketch of an observatory on the tower of a dwelling-house and surrounded by chimneys, such as that possessed by the author. The position is certainly not conducive to accurate observations, and the dome described appears to offer every opportunity for being lifted off by a high wind and deposited in the garden.

But although the first and second volumes of this work possess a few commendable features, the third volume,

has none. It bears the mark of hurried revision, and stands condemned as one of the most incomplete and incorrect productions of its kind. The title of the volume is "The Starry Heavens," and had it been written a quarter of a century ago might have contained most of the matter that is now given. In the face of this fact, which can be well substantiated, Mr. Chambers remarks, "The contents of the volume have been thoroughly revised and brought up to date, and when necessary extended and re-arranged;" yet the only reference to the important and increasing application of photography to the delineation of nebulæ is that in the case of the nebula in Andromeda: "Mr. I. Roberts has recently obtained photographs of this object which seem to combine the features exhibited by Sir J. Herschel in the engraving appended to his 'Outlines of Astronomy,' with the rifts recorded by Bond."

The curtness with which Mr. Chambers disposes of the long-exposure photographs which mark an era in the progress of astronomy is lamentable, and the comparison of them with previous observations is misleading, for the features shown in the engraving at the end of Sir J. Herschel's "Outlines" were never observed; and if Mr. Chambers has seen the photograph he must have noticed that Bond's rifts are considerably extended, and appear as divisions between masses of nebulous matter sweeping round the nucleus. At any rate a person who had not seen the photograph would scarcely be able to appreciate its beauty from the description.

We do not, of course, wish to say that, since photography has so considerably extended our knowledge of the structure of celestial species, all drawings of them should be discarded. The photographic plate only adds to their value because, by a cumulative effect, it grasps and renders manifest faint light which the eye alone can never appreciate; but this is such an important development that the hand-book in which nebulæ are described and their forms dilated upon without giving it full consideration must be stigmatized as terribly incomplete.

Again, the selection of drawings of nebulæ which Mr. Chambers made for the first edition of this work in 1867, and which is still retained, is not a happy one by the common consent of all observers; and we should have supposed that, since many elementary text-books contain reproductions of some of the photographs of nebulæ, a work of such pretensions as this, in which drawings of nebulæ may be counted by the score, would have had at least one photographic representation of their form to enrich its pages.

Also, with respect to the nebula in Andromeda, Mr. Chambers records: "Huggins has noticed the spectrum to be continuous (though cut off at the red end), and therefore, whatever it is seemingly, it is *not gaseous.*" That the spectrum was observed by Dr. Huggins in 1864 to be crossed "evidently either by lines of absorption or by bright lines," and that it has been shown to have the same spectrum as that of a comet at a mean distance from the sun, are matters with which Mr. Chambers is apparently not acquainted. It is good to see it asserted, in an italicized expression however, that the nebula does not consist of gaseous matter.

Following the chapters devoted to star clusters, nebulæ, and the Milky Way, and making up the greater portion of the work, we find catalogues of naked-eye, red, variable, and binary stars, which may be found useful. The indexes to both volumes leave much to be desired; indeed, the author notes that they are not complete by themselves, and are designed for use in connection with the table of contents. The disadvantages of this division are obvious, since reference is rendered unnecessarily difficult, a circumstance which, in the eyes of those accustomed to use works of this character, detracts considerably from its merit. At the end of the third volume a general index to the whole work is inserted which is said to be comprehensive. In this we find the names given of all the minor planets, although in the vast majority of cases the cognomen of these unimportant bodies is only known to the discoverer, and to index them is an utter waste of space. The principle, however, of including what might have been omitted and of omitting what should have been included, seems to have been followed by Mr. Chambers through each of the three volumes. We should advise, therefore, that in the case of a future edition a more careful consideration of what constitutes astronomical progress should be made. If this were done, and the facts were arranged in a rather better order, the compilation would be more useful as a hand-book of astronomy.

ANNALS OF THE MUSEUM OF BUENOS AYRES.

Annales del Museo Nacional de Buenos Aires para dar a conocer los objectos de historia natural nuivos ó poco conocidos conservados en este establecimento. Por German Burmeister, Med. Dr., Phil. Dr., Director del Museo Nacional de Buenos Aires. Entrega decimasexta. (Buenos Aires, 1890.)

THE veteran man of science, Dr. H. Burmeister, of Buenos Ayres, continues to issue the "Annals" of the Museum under his charge with unfailing regularity, and now sends us a copy of the 16th part of this excellent serial. Upon the present occasion he deserts for a while his favourite subject of the fossil animals, which the Argentine Tertiaries produce in such countless abundance and of so strange a character, and gives us an account of a scientific expedition into Patagonia, recently carried out by his son, Sr. Carlos V. Burmeister, one of the assistant naturalists of the Museum.

The scientific staff of the expedition to Patagonia left Buenos Ayres in November 1888, and proceeded by railway to Bahia Blanca, and thence by diligence to Carmen on the Rio Negro, where the rest of the party was assembled. The next point attained was Trelew, the chief town of the Welsh settlement on the Rio Chubut, which is now connected by a railway, 70 kilometres in length, with Port Madryn on the Atlantic. By this route, various additional stores, forwarded direct from Buenos Ayres by steamer, were received, and the Expedition, being fully equipped, finally started for the interior of Patagonia on January 9, 1889. The route taken was up the valley of the Chubut until its junction with its tributary, the Rio Chico, whence the latter was followed to its source in the great Lake Colhue. Although the country surrounding this sheet of water is now utterly devoid of trees of any sort, this was certainly not the case in past times, as

enormous trunks of fossil trees were observed on the shores of the lake. From Lake Colhue the Rio Singuer which flows into it was ascended, until a point was reached where this stream takes an abrupt bend to the north-west. Thence the route lay for many days through the unknown uplands of the interior, until the upper waters of the Rio Chico de Santa Cruz were struck in lat. 48° 55′ 15″ S., on the last day of February. Descending the Rio Chico de Santa Cruz, the Expedition reached Beagle Bluff at the mouth of the great Santa Cruz, on March 9. Beagle Bluff, we may remind our readers, was so named from H.M.S. *Beagle*, which visited the spot in 1834, and first explored the River Santa Cruz. Darwin, who accompanied the boats of the *Beagle* in their survey of this stream, came to the conclusion that the river-valley of the Santa Cruz was formerly a strait dividing South America right across at this point, like the Straits of Magellan do now further south (see Darwin's "Naturalist's Voyage," chap. ix.).

The interior of Patagonia traversed by Sr. Burmeister's Expedition appears to be almost deserted at the present time. No natives seem to have been met with between the Chubut and the Rio Chico de Santa Cruz until the lower part of that river was reached.

From Port Santa Cruz the Expedition returned northwards along the Atlantic coast to Port Deseado in lat. 47° 56′, and thence, ascending the river of the same name, rejoined their former route on the Rio Singuer.

Besides the accurate survey made during the expedition, a large number of photographic views were taken, a selection of which will be published subsequently. These will be of interest in connection with the question of the origin of the singular "basaltic terraces" of this country, of which Darwin gave us the first indication, and which are frequently referred to by Señor Burmeister. Large collections were also made in natural history, most of which await further examination. But articles on the mammals and birds obtained during the expedition are appended to the present Report. Most of these are referred to species already fairly well known, although an exception must be made in favour of *Canis griseus*—the smaller of the two native foxes of Patagonia, of which little, if anything, has been recorded since its accurate description by Dr. H. Burmeister was published some years ago. The remaining collections still to be worked out will probably be found to contain objects of greater rarity; but there can be no doubt that the Patagonian fauna, though of great interest, is rather meagre.

OUR BOOK SHELF.

The Triumph of Philosophy. By James Gillespie (Ealing: West Middlesex Printing and Publishing Co. 1890.)

THE author has endeavoured to correct the Copernican theory of astronomy, and propounds instead the Gillespian or true system of the universe, which asserts that the earth, as well as the sun, is fixed in space and all the stars revolve round it in a year.

One of the objections to the present arrangement reads as follows:—

"Can any man in his sober senses believe that the earth could fly through space at the rate of 1000 miles a minute. Would it not drive all the atmosphere either away from the earth or like the tail of a comet? Could the moon keep her constant path round the earth at 273,000 miles distant, if she (the earth) was flying at this terrific speed?"

To understand this argument, it is necessary to believe with Mr. Gillespie that gravitation has nothing to do with the motions of any of the heavenly bodies. In his words:

"I admit gravitation on the earth, but it only extends a certain distance from the earth, and it is quite powerless at the moon's distance, otherwise the moon—if she has weight at all—would fall crash on to the earth."

The greater portion of the work is taken up with observations of Mr. J. B. Dimbleby, of the British Astronomical Society (*sic*). This gentleman, whose genius seems shrouded in obscurity, is styled "Transit Medallist, Professor of Chronology, first calculator of all eclipses and transits from Adam, and the discoverer of five lines of astronomical time." We give a short extract, in which some of his researches are referred to:—

"He has proved, by a long and by a true calculation, that the earth, the sun, the moon, Mercury, and Venus were all in one direct line at creation, and it is almost likely that the other planets were in the same position, and there they would stand like a team of racehorses till the Divine signal was given, and off they went each on his own course; and it has been proved by eclipses and transits, ancient and modern, that they have not varied a single minute since that great day."

It will be readily understood that to try to convince Mr. Gillespie of the unsoundness of his arguments would be the height of absurdity, since he has not even an elementary knowledge of physical laws. As in all similar productions, strong words and hearty abuse are indulged in to patch up weakness of argument; no one is disturbed by the tirade, however, and the Gillespian doctrine of the universe will doubtless pass away with Mr. Dimbleby and its originator.

Watch and Clock Making in 1889. By J. Trippling, F.R.A.S., &c. (London: Crosby Lockwood and Son, 1890.)

THIS little book consists of an account and comparison of the exhibits in the horological section of the French International Exhibition.

In England there is very little literature on this subject, but on the Continent, and in France especially, a great many works on it have been published. The chief textbook is that by M. Saunier, who has done much towards the elevation of the social position of watchmakers, and whose books are the standard works of reference on the Continent.

Twelve technical schools competed against one another at the Exhibition; great importance being attached to the technical teaching of this class of subject abroad. An excellent programme of the work which is done during the student's course is given by the author, and shows the method of teaching that is adopted.

Chronograph makers are next dealt with; of these there were twenty representatives, four being English. For performance, finish, and the number of instruments produced, England was awarded the palm. The tests which instruments of this kind have to undergo are more severe in England than in Switzerland, owing to the greater variation in temperature. For instance, one English chronometer went for twenty-eight weeks with a variation never exceeding 1·4 seconds; while a Swiss chronometer, cited as being an exceptionally good one, varied as much as 2·2 seconds in two weeks.

The next section treats of the manufacture of watches, and in this one hundred and fifty firms exhibited. This number was divided into two classes—"factory system" and "garret system"; the former consisting of those who manufactured them by using steam and hydraulic power

for the output of the whole or part of the watch on the interchangeable system, the latter of those who still kept to the old mode of making them "under a system of subsetting to small makers who work at their own homes."

Messrs. Rotheram and Sons, of Coventry, about the oldest and the largest firm of watch manufactures in England, headed the list, and seem to have had a fine display, theirs being one of the most striking exhibits in the Exhibition.

In the remaining pages the author gives an account of the merits and exhibits in the manufacture of clocks, turret clocks, tools, watch-cases, &c., concluding with a short summary.

On the whole, the British section seems to have fared very well, and to have held its own against foreign competition, and to those interested in the subject this work will afford a good insight into the present condition of watch and clock making.

The Harpur Euclid. Books V., VI., and XI. By E. M. Langley, M.A., and W. Seys-Phillips, M.A. (London: Rivingtons, 1890.)

THIS is an edition of Euclid's Elements revised in accordance with the reports of the Cambridge Board of Mathematical Studies and the Oxford Board of the Faculty of Natural Science.

The books dealt with are V., VI., and XI.

In most of the works on this subject Book V. is generally omitted, and only the definitions are learnt; but the authors have thought it advisable for the reader to acquaint himself with the terms used and with some of the theorems which are established in it. Although he is allowed to use these theorems as axioms, proofs are given depending on the definitions, the notation used being that recommended by De Morgan and adopted by the Association for the Improvement of Geometrical Teaching in its Syllabus and Elements.

Preceding Book XI. is a good and well worked out series of propositions on loci, harmonic division, similarity, maxima and minima; and a few miscellaneous problems, such as the nine-point circle, &c.

The proofs in Book XI. differ slightly from those ordinarily given in text-books, but are made shorter and perhaps clearer by the adoption of symbols.

The method throughout of dotting all construction lines is a great help to the reader, and is to be heartily recommended, the figures in Book XI. showing this off to advantage.

A large number of exercises are given here and there for the student to practise his ingenuity on.

The International Annual of Anthony's Photographic Bulletin, 1890-91. Edited by W. Jerome-Harrison and A. H. Elliott. (London: Iliffe and Son, 1890.)

THIS is the third volume that has been published of this most interesting Bulletin, and, glancing through its pages, we conclude that it is one of the best publications of its kind that we have come across. The articles, written in great part by men of acknowledged ability, contain a large amount of useful knowledge, forming a store of information from which workers in every rank of the art may obtain something that will interest them.

One of the chief features of the volume is the great increase in number of illustrations, which are printed by the various kinds of processes now available, and which show the advancement made in the application of photography for purposes of illustration.

The usual collection of tables is presented at the end. Among them may be mentioned Dr. Woodman's table of view angles, tables for the simplification of emulsion calculations, and tables of comparative exposures. The work concludes with a revised list of the Photographic Societies of the British Isles, British Colonies, America, and most of those on the Continent.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Discharge of Electricity through Gases.

IN the Bakerian lecture on "The Discharge of Electricity through Gases," in the last number of the Proceedings of the Royal Society, Prof. Schuster says:—"I do not see how the insulating power of air at the ordinary temperature is consistent with the presence of ions, however few in number, for ultimately a diffusion to the electrodes and a discharge would necessarily take place. This seems to me to be fatal to J. J. Thomson's view of the disruptive discharge."

This statement implies a misconception of the theory of the electric discharge advanced by me in the *Philosophical Magazine*, June 1883, for there is nothing in the theory of the discharge there given which makes the presence of free ions in air at ordinary temperatures and pressures essential. I will quote two sentences from the paper to show what the theory is:—"In order to make the spark pass through an elementary gas, we have to decompose the molecules into atoms. Thus the stronger the connection between the atoms in the molecules, the greater the electric strength." "Chemical decomposition is not to be considered merely as an accidental attendant on the electrical discharge, but as an essential feature of the discharge, without which it could not occur."

The misconception has, no doubt, arisen from my using in the same paper the Clausius-Williamson hypothesis of the interchange of atoms among the molecules to account for the difference of pressure in different directions in the electric field. But this hypothesis is not essential to the theory of the *discharge* given in the paper, for on that theory the discharge does not take place until *ordinary* dissociation of the molecules is produced by the electric field. The existence or non-existence of the quasi-dissociation of the Clausius-Williamson hypothesis which does not produce any chemical effects, does not affect the theory of the discharge, though it does that of the inequality of pressure. J. J. THOMSON.

Cambridge, July 19.

Birds and Flowers.

IN your note on Mr. G. F. Scott-Elliot's paper on this subject (NATURE, July 17, p. 279) you remark: "In accordance with the view of Darwin, but opposed to that of Wallace, Mr. Scott-Elliot believes that the identity of colour (an unusual shade of red) in the majority of ornithophilous flowers and on the breasts of species of *Cinnyris* is an important element in pollination by birds." There must be, I think, some misapprehension here. I am not aware that Darwin has anywhere referred to the colours of birds as being generally similar to those of the flowers they frequent. Mr. Grant Allen has done so in his work on "The Colour-Sense," and I have opposed his views in NATURE (vol. xix. p. 501), because he founds the resemblance on the theory of sexual selection, and because the facts do not support any such general relation. That such a relation does sometimes occur I have shown, by quoting Mrs. Barber in my "Darwinism" (p. 201) as to the scarlet and purple colours of a sun-bird being highly protective when feeding among the similarly coloured blossoms of the *Erythrina caffra*, which, at the time, has no foliage. I have also called attention (in the same work, p. 319) to the numerous flowers now known to be fertilized by birds, and to the numerous large tubular flowers of a red and orange colour in Chile and the Andes, which are apparently adapted to be fertilized by humming-birds. The general uniformity of colour would be advantageous as an indication of bird-flowers as distinguished from insect-flowers; but there is no similarity to the colours of the birds. Curiously enough, the common Chilian Eustephanus is green-coloured in both sexes, while its close ally in Juan Fernandez is red in the male. Yet the flowers it frequents in the island are not red, but mostly white and yellow (see "Tropical Nature," p. 272). It is evident, therefore, that the prevalent colours of the flowers do not determine the colours of the birds which frequent them, unless those colours are so predominant that a similar colour becomes protective, as is more generally the case in the scantily-wooded plains of South Africa than anywhere else. ALFRED. R. WALLACE.

Reduplication of Seasonal Growth.

FROM time to time instances of this in the case of foliage have been recorded by correspondents in the pages of NATURE. This year I have noticed not only an unusually early appearance of this in the development of new foliage-laden twigs, as in former years in the oaks, the hornbeams, the elms, and other forest trees; but, what is more rare with this somewhat exceptional summer, the fruit-trees seem to be expending their reserve energy in a second season of *flowering*. At this moment an apple-tree in my garden presents the curious sight of apple-blossoms side by side with apples more than half-grown, and a rowan-tree laden with nearly ripe fruit has a corymb of flowers on one of its higher boughs. The plum-trees have presented similar abnormal phenomena within the last week or two. The facts are of interest as pointing to considerable interference with the normal cycle of functional change by variations in environment.

Wellington College, Berks, July 18. A. IRVING.

Chimpanzees and Dwarfs in Central Africa.

PERHAPS Mr. Stanley or Surgeon Parke, if applied to, could throw some more light on the extraordinary statement made by Emin Pasha, recently referred to, which, if it be true, is the most important statement in the whole book.

It is probable that when Emin Pasha witnessed the torch-bearers, whether chimpanzees or young negroes or dwarfs, he was not alone, and, even though very short-sighted, he would have been able to verify his observation of the torch-bearing animals by reference to those near him. An experienced naturalist like Emin Pasha is not likely to have made the mistake Prof. Romanes thinks he did make—but it is possible.

Bearing in mind that a large ape is now undoubtedly acting as a signalman (under direction) on a railway at Natal, who can say what the limits of intelligence are in the tribes of Simians?

J. F.

The Perseid Meteors.

ACCORDING to Mr. Denning, the radiant of the famous Perseid meteor-shower (which, in his opinion, commences early in July) shifts night after night until about August 20, the principal change being an increasing R.A. The declination also increases, but more slowly.

I have some reason to think that the true explanation of the phenomena is that there are several radiants almost simultaneously in action, but which do not attain their maxima at the same data. For this reason I would ask those of your readers who are interested in the subject to watch these meteors carefully on the present occasion. W. H. S. MONCK.

Dublin, July 15.

P.S.—Mr. Denning's Catalogue in *Monthly Notices* for May suggests to me the existence of four radiants (each of some continuance) whose approximate positions are 6° + 52°, 20° + 57°, 32° + 53°, and 44° + 56°.

"Wind Avalanches."

SOME of the readers of Dr. Pernter's paper, "A Winter Expedition to the Sonnblick," may perhaps be interested by the following extracts from the *Alpine Journal* of June 1864. They are taken from a painfully interesting paper by Mr. Gosset, describing a fatal accident on the Haut-de-Cry in February of that year.

A party of six were crossing a wide *couloir*, "about 150 feet broad at the top and 400 or 500 at the bottom." The actual fall of the avalanche is thus described:—"Bennen advanced; he had made but a few steps when we heard a deep, cutting sound. The snow-field split in two about 14 or 15 feet above us. The cleft was at first quite narrow—not more than an inch broad. An awful silence ensued . . . broken by Bennen's voice: 'Wir sind alle verloren.' . . They were his last words. I drove my alpenstock into the snow, and brought the weight of my body to bear on it. . . . I turned my head to see whether Bennen had done the same thing. To my astonishment, I saw him turn round, face the valley, and stretch out both arms. (So in Dr. Pernter's paper, "Their advice is to throw oneself prostrate, with hands outstretched.") The ground on which we stood began to move slowly, and I felt the utter uselessness of any alpenstock. I soon sank up to my shoulders, and began descending backwards. . . . The speed of the avalanche increased rapidly, and before long I was covered up with snow. I was suffocating when I suddenly came to the surface again. I was on a wave of the avalanche, and saw it before me as I was carried down. . . . The head alone was preceded by a thick cloud of snow-dust; the rest of the avalanche was clear. Around me I heard the horrid hissing of the snow, and far before me the thundering of the foremost part of the avalanche. . . . At last I noticed that I was moving slower; then I saw the pieces of snow in front of me stop at some yards' distance; then the snow straight before me stopped. . . . I felt that I also had stopped, . . . but the snow behind me was still in motion; its pressure on my body was so strong, that I thought I should be crushed to death."

Mr. Gosset further remarks:—"The upper stratum of snow was eleven days old. . . . The snow was thawing, and the whole snow-field in a state of uncertain equilibrium. By cutting through the snow at the top of the *couloir* we cut one of the main points by which the snow of the two different layers held together. . . . The avalanche may have taken a minute to descend; I can give no correct estimation on this point."

The vividness of the above description, and its complete accord with Herr Rojacher's account given in Dr. Pernter's paper, will, I hope, excuse the length of the extracts.

Otham, Maidstone. F. M. MILLARD.

ON THE METEOROLOGICAL CONDITIONS OF DESERT REGIONS, WITH SPECIAL REFERENCE TO THE SAHARA.[1]

THE arid regions of the world are, speaking roughly, distributed in two bands north and south of the equator. They comprehend all inland drainage areas, or areas where the streams have no connection with the sea, which are also regions where evaporation is in excess of precipitation, for if the latter were in excess the water would rise till it could flow into the sea, as in the case of the great lake region of North America, and the area would no longer be one of inland drainage. The largest of the deserts, the Sahara, is about 3½ million square miles in area, and the area of all the deserts of the world together about 11,500,000 square miles. In other words, over one-fifth of the land of the world has no outlet for drainage to the sea, and in all that area evaporation is greater than precipitation. These areas correspond very closely with the regions of the world where the rainfall is less than 10 inches annually.

In no place in the world can there be found such enormous ranges of temperature as in these deserts. In the Sahara the temperature sometimes falls from 100° during the day to the freezing-point during the night, due to the great dryness of the atmosphere and to the radiation that takes place from the soil after the sun has set. These inland drainage areas correspond very much in their barometric phenomena. In all desert regions during summer all the winds blow in upon them. In winter the reverse takes place—the winds flow out of them, and that holds good both for the northern and the southern hemispheres. This occasions the low rainfall, for the great majority of these regions are more or less bounded by high hills. The winds arrive at the deserts over these hills, and the vapour is precipitated from the atmosphere by the hills, with the result that when the winds reach the interior regions there is nothing left to be deposited. If there are not hills all round any desert area, then, as in the case of Northern Asia, the winds pass from a colder to a warmer climate, and as they get to warmer regions they are able to contain more vapour, and, consequently, no rain is precipitated.

The author then gave an account of his own views and impressions as to the Sahara. When staying in May last in Algeria, he was anxious to make a trip to the desert, principally with the object of examining the sand and other deposits. During the *Challenger* expedition they had found in the bed of the Atlantic for a long distance

[1] Abstract of a Paper read by Dr. John Murray at the meeting of the Scottish Meteorological Society held in Edinburgh on July 14.

west of the African coast opposite the Sahara, and in the bed of the Indian Ocean to the south of Australia, small grains of red quartz sand, and they had found scarcely a trace of such in the sea-bed in any other part of the world. He suspected this quartz sand had been blown out from the Sahara in the one case, and from the Australian desert in the other.

In the south of Algeria he got a light carriage which could traverse the desert, such as was now in use for the post just established by the French to Tougourt, in the Sahara. Taking bedding and food with him, he first skirted a large area covered with salt, and then passed on through the long belt of oases which the French have planted on the way to Tougourt. Along this route numerous artesian wells had been sunk, and an abundant supply of water thereby obtained for the palm-trees which had been planted. There were now three companies in existence, who had dug artesian wells, and were planting thousands of palm-trees, with the view of getting a valuable return in a few years.

At Tougourt the real sandy part of the desert began, and he made excursions into it, with that town as his head-quarters. He exhibited to the meeting a specimen of the sand, of a light yellowish-brown colour, and exceedingly fine in the grains. There were a good many clay particles in it, and the quartz particles, which were also numerous, were identical with those they had got in the bottom of the Atlantic. There was no doubt that the winds from the desert carried the sand a long way out to sea. He had also examined the region geologically, and the formation of the rocks was entirely that of fresh water, and of Quaternary date.

The great majority of geographers and geologists had expressed the belief that the Sahara was an old sea-bed, but he was of opinion that it had never as a whole been covered by the sea since Cretaceous or Devonian times, and no part of it had been covered by the ocean since Tertiary times. All the assertions as to the discovery of shells rested upon one common species being found very rarely in one region of the desert. He thought that, owing to recent researches, the opinion as to the Sahara being an old sea-bottom was likely soon to disappear from our text-books. He considered that the features of the region had been produced by atmospheric conditions. The sand was the product of the disintegration of the rocks *in situ*, which engirdle the Sahara. The existing rock was not far below the surface, and, by digging down to it, the hard sandy particles were found embedded in the stone. The sun shone on the rocks, and they expanded. The sudden cooling at night broke them up, the wind carried away the smaller particles, and so continually the rocks were being disintegrated by means of changes other than water, although water perhaps had in times past played a greater *rôle* there than it did now.

There was a range of hills in the desert to the south 7000 feet high, and for three months in the year their summits were covered with snow. Descending the hills were river-courses, some of great length. Much of the region, he considered, had once been a large fresh-water lake. Speaking of the commercial aspect of the Sahara, he said it was difficult to go there without becoming enthusiastic about it. There seemed to be no limit to the amount of water that was to be got by sinking artesian wells. The head of the water must be a long distance away in the higher lands surrounding the desert.

The cultivation of palms was extending to an enormous extent, and the French expected to carry on their railway to Tougourt (at present nearly a week's journey from Algeria) in the next few years. The French were also hopeful that France would tap all the trade of the North Soudan across the Sahara, by making a railway across the desert. He did not think it was at all impossible to build and keep open such a railway. There was plenty of water to be had, and the sand never drifted to such an extent as to bury a railway. The climate, though very warm, was at the same time very healthy. If the French built the railway, they would then have no cause to complain about Britain remaining in Egypt.

WILLIAM KITCHEN PARKER, F.R.S.

WILLIAM KITCHEN PARKER was born at Dogsthorpe, near Peterborough, June 23, 1823, and died suddenly, of syncope of the heart, July 3, 1890. He was visiting his second son, Prof. W. N. Parker, at Cardiff, and, whilst cheerfully talking of late discoveries and future work in his favourite biological pursuits, he ceased to breathe. Accustomed to outdoor life, he was a true lover of Nature from the first; the forms, habits, and songs of birds, especially, he knew at an early age. Village schooling at Dogsthorpe and Werrington, and a short period at Peterborough Grammar School, prepared him for an apprenticeship, at 15 years of age, to Mr. Woodroffe, chemist and druggist at Stamford; and three years afterwards he was apprenticed to Mr. Costal, medical practitioner, at Market-Overton. At Stamford he studied botany earnestly, and used to persuade a fellow-apprentice to leave his bed in early mornings to go afield in search of plants. Both when living at his father's farm, and in his holidays afterwards, he kept many pet animals, and dissected whatever he could get, including a donkey and many birds. Of the latter he prepared skeletons; and of these he made many large drawings, at Market-Overton, which of late years he had some thought of publishing as an atlas of the osteology of birds. In 1844-46 he studied at King's College, London; and became student-demonstrator to Dr. Todd and Mr. (now Sir William) Bowman there. He also attended at Charing Cross Hospital in 1846 and 1847, and, having qualified as L.S.A., he commenced practice, in 1849, at Tachbrook Street, Pimlico; and soon afterwards married Miss Elizabeth Jeffery. His wife's patient calmness under all difficulties and trials was a true blessing to a man of Mr. Parker's excitable temperament; and her unselfish life and widespread influence for good are well known in and beyond the family circle. Unfortunately he was left a widower about four months ago. His family consists of three daughters and four sons. Of the latter, one is Professor of Zoology and Comparative Anatomy in the University of Otago, New Zealand; the second is Professor of Biology in the University College at Cardiff, South Wales; the third is an able draughtsman and lithographer; and the fourth has lately taken his diplomas of L.R.C.P. and M.R.C.S.

Mr. Parker had a good father, courteous and gentle by nature, conscientious, and earnest in business, who had worked hard to be able to give even his youngest son, Mr. W. K. Parker, "a start in life." From his placid and thoughtful mother he probably inherited much of his love of reading and his talent for learning.

Always energetic, in spite of constant ill-health, Mr. Parker enthusiastically carried on his medical work and his natural-history studies, especially in the microscopic structure of animal and vegetable tissues. Polyzoa and Foraminifera, collected on a visit to Bognor, and from among sponge-sand and Indian sea-shells, especially attracted his attention. Having sorted, mounted, and drawn numbers of these microzoa, he was induced, about 1856, by his friends W. Crawford Williamson and T. Rupert Jones, to work at the Foraminifera systematically. His paper on the *Miliolitidæ* of the Indian Seas (Trans. Micros. Soc., 1858), and a joint paper (with T. R. Jones) on the Foraminifera of the Norwegian coast (*Annals N. H.*, 1857) resulted; and the latter formed the basis of a memoir on the Arctic and North-Atlantic Foraminifera (Phil. Trans., 1865). With T. Rupert Jones, and after-

wards with W. B. Carpenter and H. B. Brady, Mr. Parker, down to 1873, described and illustrated many groups and species of Foraminifera, recent and fossil (see C. D. Sherborn's "Bibliography of Foraminifera" for these papers and memoirs), thereby establishing more accurately a natural classification of these microzoa, determining their bathymetrical conditions, and therefore their value in geology. That he did not neglect anatomical research is shown by memoirs in the Proceedings and Transactions of the Zoological Society on the osteology (chiefly cranial) and systematic position of Balæniceps (1860), Pterocles (1862), Palamedea (1863), Gallinaceous Birds and Tinamous (1862 and 1866), Kagu (1864 and 1869), Ostriches (1886), Microglossa (1865), Common Fowl (1869), Eel (NATURE, 1871), skull of Frog (1871), of Crow (1872), Salmon, Tit, Sparrow-hawk, Thrushes, Sturgeon, and Pig (1873). In the meantime the Ray Society had brought out his valuable "Monograph on the structure and development of the Shoulder-girdle and Sternum in the Vertebrata" (1868); and his Presidential addresses to the Royal Microscopical Society (1872, 1873), and notes on the Archæopteryx (1864), and the fossil Bird bones from the Zebbug Cave, Malta (1865 and 1869), had been published. Subsequently the Royal Society's Transactions contained his abundantly illustrated memoirs on the skull of the Batrachia (1878 and 1880), of the Urodelous Amphibia (1877), the Common Snake (1878), Sturgeon (1882), Lepidosteus (1882), Edentata (1886), Insectivora (1886), and his elaborate memoir on the development of the wing of the Common Fowl (1888). In the "Reports of the *Challenger*" is his memoir on the Green Turtle (1880); and those on Tarsipes (Dundee, 1889), and the Duck and the Auk (Dublin, 1890), are his last works.

In former times a skull was taken as little more than a dry, symmetrical, bony structure; or, if it were the cartilaginous brain-case of a shark, it was to most a mere dried museum specimen. When, however, the gradations of the elements of the skull, from embryonic beginnings, were traced until their mutual relations and their homologues in other Vertebrates were established, light was thrown on the wonderful completeness of organic uniformity and singleness of design. How such studies can be carried on both by minute dissection and the modern art of parallel slicing, and not by one method alone, is to be gathered from his teaching.

Mr. Parker was elected a Fellow of the Royal Society in 1865, and in the year following he received a Royal Medal for his comprehensive, exact, and useful researches in the developmental osteology, or embryonal morphology, of Vertebrates. Some few years afterwards the Royal Society gave him an annual grant to aid in the prosecution of his studies; and, when that was discontinued, a pension from the Crown was graciously and appropriately awarded to him. A generous friend, belonging to a well-known Wesleyan family, more than once presented £100 towards the cost of some of the numerous plates illustrating his grand memoirs in the Philosophical Transactions.

In 1873 he received the diploma as Member of the Royal College of Surgeons, and was appointed Hunterian Professor, Prof. Flower being invalided for a time; and afterwards both held the Professorship conjointly. His earnestness and wide views were well appreciated, opening up the modern aspect of comparative anatomy, and showing that both in Man and the lower Vertebrates the wonderful structural development of their bony framework should be studied in a strictly morphological rather than a teleological method, and that its stages and resultant forms could be regarded only in the Darwinian aspect.

These lectures, given in abstract in the medical journals, became the basis of his "Morphology of the Skull," in writing which, from his dictation and notes, Mr. G. T. Bettany kindly assisted him; and again, in a semi-popular book, "On Mammalian Descent," another friend (Miss Arabella Buckley, now Mrs. Fisher) similarly helped him. In the latter work, his own usual style frequently predominates, full of metaphor and quaint allusions, originating in his imaginative and indeed poetic mind, fully impregnated with ideas and expressions frequent in his favourite and much-read books—Shakespeare, Bacon, Milton, some of the old divines, and, above all, the old English Bible.

Separating himself from the trammels of foregone conclusions, and from the formulated, but imperfect, misleading conceptions of some of his predecessors in Biology, whom he left for the teaching of Rathke, Gegenbaur, and Huxley, Prof. W. K. Parker earnestly inculcated the necessity of single-sighted research, and the following up of any unbiassed elucidations, to whatever natural conclusion they may lead. Simple and firm in Christian faith, resolute in scientific research, he felt free from dread of any real collision between science and religion. He insisted that "our proper work is not that of straining our too feeble faculties at system-building, but humble and patient attention to what Nature herself teaches, comparing actual things with actual" (Proc. Zool. Soc., 1864); and in his "Shoulder-girdle, &c.," p. 2, he writes: "Then, in the times to come, when we have 'prepared our work without, and made it fit for ourselves in the field,' we shall be able to build a 'system of anatomy' which shall truly represent Nature, and not be a mere reflection of the mind of one of her talented observers."

Again, at p. 225, in illustration of some results of his work, he says:—"The first instance I have given of the Shoulder-girdle (in the Skate) may be compared to a clay model in its first stage, or to the heavy oaken furniture of our forefathers, that 'stood pond'rous and fixed by its own massy weight.' As we ascend the vertebrate scale, the mass becomes more elegant, more subdivided, and more metamorphosed, until, in the Bird Class and among the Mammals, these parts form the framework of limbs than which nothing can be imagined more agile or more apt. So also, as it regards the Sternum; at first a mere outcropping of the feebly developed costal arches in the Amphibia, it becomes the keystone of perfect arches in the true Reptile; then the fulcrum of the exquisitely constructed organs of flight in the Bird; and, lastly, forms the mobile front-wall of the heaving chest of the highest Vertebrate."

Prof. W. K. Parker was a Fellow of the Royal, Linnean, Zoological, and Royal Microscopical Societies; Honorary Member of King's College, London, the Philosophical Society of Cambridge, and the Medical Chirurgical Society. He was also a Member of the Imperial Society of Naturalists of Moscow, and Corresponding Member of the Imperial Geological Institute of Vienna, and the Academy of Natural Sciences of Philadelphia. In 1885 he received from the Royal College of Physicians the Bayly Medal, "Ob physiologiam feliciter excultam."

In conversations shortly before his death, he often spoke of looking forward throughout his life-time (alas! how quickly shortened!) to continued application of all the energy he could devote to his useful work—at once a consolation to him and a duty.

He has well expressed his own view of biological pursuits, at p. 363 of the "Morphology of the Skull":—"The study of animal morphology leads to continually grander and more reverend views of creation and of a Creator. Each fresh advance shows us further fields for conquest, and at the same time deepens the conviction that, while results and secondary operations may be discovered by human intelligence, 'no man can find out the work that God maketh from the beginning to the end.' We live as in a twilight of knowledge, charged with revelations of order and beauty; we steadfastly look for a perfect light, which shall reveal perfect order and beauty."

An unworldly seeker after truth, and loved by all who

knew him for his uprightness, modesty, unselfishness, and generosity to fellow-workers, always helping young inquirers with specimens and information, he was suddenly lost to sight as a friend and father, but remains in the minds of fellow-workers, of those whom he so freely taught, and of his stricken relatives, as a great and good man, whose beneficent influence will ever be felt in a wide-spreading and advancing science, and among thoughtful and appreciative men in all time.

ALPHONSE FAVRE.

BY the death of Prof. A. Favre, Switzerland has been deprived of one of her foremost men of science, and geology has lost a very assiduous and successful cultivator. His death appears to sever the last remaining link between the present generation of Swiss geologists and that older and famous one which included Bernhard Studer, Arnold Escher von der Linth, Peter Merian, and Oswald Heer. The late Prof. Favre, who had reached the age of seventy-seven at the time of his death, was the author of numerous papers, the earliest of which, "On the Anthracites of the Alps," was published as long ago as 1841. He will perhaps be best remembered by the part he took in the famous controversy concerning the supposed admixture of fossils, belonging to different geological horizons, which were said to occur in the same beds in the Alps. In opposition to M. Scipion Gras and others who asserted that such intermixture of fossils did actually occur, Favre was able to show, by a series of patient investigations, that the apparent reversals of succession, and intimate union of Carboniferous, Jurassic, and Tertiary strata, could all be accounted for by repeated interfoldings and complicated overthrust faults. It is interesting to note that at the time when Favre was thus successfully contending for such an interpretation of supposed anomalies in the Alpine rocks, James Nicol in this country was engaged in a precisely similar controversy with Murchison and his followers, concerning the rocks of our own Highlands. But whereas the triumph of Favre's views was immediate and complete, and their author lived to see the justice of his interpretation universally admitted, Nicol was fated to witness the influence of great authority exerted for a long time in preventing the truth of his conclusions from being accepted; and only after his death was the retraction made which showed how much Scotland owes to this able interpreter of the geological structure of his native land. History may be relied upon, however, to do equal justice to the successful Swiss geologist and the disappointed Scotch one. Prof. Favre, besides papers on a great variety of geological questions, wrote several works dealing with the geology of the parts of Savoy, Piedmont, and Switzerland of which Mont Blanc forms the centre. During the later years of his life he had retired from his Professorship of Geology at Geneva, but up to the time of his death Favre held the post of President of the Federal Commission having charge of the geological map of Switzerland. As long ago as 1874 he was elected a foreign member of the Geological Society, and he was also a correspondent of the Institute of France.

AID TO ASTRONOMICAL RESEARCH.

PROF. PICKERING, of the Harvard College Observatory, has issued the following notice:—

"Miss C. W. Bruce offers the sum of six thousand dollars ($6000) during the present year in aiding astronomical research. No restriction will be made likely to limit the usefulness of this gift. In the hope of making it of the greatest benefit to science, the entire sum will be divided, and in general the amount devoted to a single object will not exceed five hundred dollars ($500). Precedence will be given to institutions and individuals whose work is already known through their publications, also to those cases which cannot otherwise be provided for, or where additional sums can be secured if a part of the cost is furnished. Applications are invited from astronomers of all countries, and should be made to the undersigned before October 1, 1890, giving complete information regarding the desired objects. Applications not acted on favourably will be regarded as confidential. The unrestricted character of this gift should insure many important results to science, if judiciously expended. In that case it is hoped that others will be encouraged to follow this example, and that eventually it may lead to securing the needed means for any astronomer who could so use it as to make a real advance in astronomical science. Any suggestions regarding the best way of fulfilling the objects of this circular will be gratefully received. "EDWARD C. PICKERING.

"Harvard College Observatory, Cambridge, Mass., U.S.A., July 15, 1890."

NOTES.

THE American Association for the Advancement of Science will meet this year at Indianapolis, under the presidency of Prof. Goodale. The first meeting will be held on August 19. The subject selected in advance for special discussion is "The Geographical Distribution of North American Plants," and papers upon it will be presented by Messrs. Watson, Macoun (of Ottawa), Sargent, Britton, Underwood, Halsted, and Coulter.

A ROYAL COMMISSION has been appointed to inquire and report "what is the effect, if any, of food derived from tuberculous animals on human health, and, if predjudicial, what are the circumstances and conditions with regard to the tuberculosis in the animal which produce that effect upon man." Lord Basing is chairman. The other Commissioners are Prof. G. T. Brown, Dr. George Buchanan, Mr. Frank Payne, and Prof. Burdon Sanderson.

THE Turin Academy of Medicine has proposed the following theme for the Riberi Prize of about £750: "Researches on the nature and the prophylaxis of one or several infectious diseases of man." Works may be sent printed or in manuscript; they may be in Italian, French, or Latin; and printed works must have appeared since 1886. The date limit is December 31, 1891.

THE failure of the Government to carry its scheme for the extinction of some public-house licences is likely to result in an important advantage to education. In his statement on Monday with respect to the money which was to have been applied to this object, Mr. Goschen said:—"As regards England we propose to add the amount set free by the abandoned licensing clauses to the residue which, under the Bill as it stands, goes to the county councils, accompanying this inclusion by an intimation that possibly new charges may, by and by, be put upon them, with reference to intermediate, technical, or agricultural education. It seems very desirable, if more is to be done in this respect, that the localities, and especially county councils, should be interested in the work. In England there is at present little machinery available for carrying out such an object, and it would be impossible to create such a machinery at this period of the session. But in Wales and in Monmouthshire the machinery does exist. County councils may supply funds to the joint committee for intermediate education under the Act of last year out of the county rate, but to the extent of a halfpenny of such rates only. We shall propose that the county councils in Wales

should have authority to increase the sum out of the additional funds now placed at their disposal. . . . As regards Ireland we shall propose that the £40,000 which falls to her share should be utilized for the further promotion of intermediate education, and for this purpose should be placed at the disposal of the Intermediate Education Board for Ireland, a body which, I believe, commands the confidence of the Irish public generally, irrespective of political and religious differences." The Government propose that the £50,000 which falls to the share of Scotland shall be handed over unconditionally to the county councils; but Mr. Campbell-Bannerman has given notice that he will move an amendment to the effect that the money be devoted directly to the completion of a scheme of free primary education.

THE Drapers' Company, London, has contributed £3000 towards the cost of the new buildings for technical instruction in connection with Nottingham University College. This branch of the College will be under the care of the recently-appointed Professor of Mechanical Engineering and Technology, Mr. William Robinson, late chief assistant at the City and Guilds Technical College, Finsbury.

A PUBLIC MEETING was held at the Town Hall, Kensington, yesterday, under the presidency of the Hon. and Rev. E. Carr Glynn, to consider measures whereby the technical and scientific education of apprentice and other plumbers may be ensured.

LAST week the Institute of Electrical Engineers held a series of meetings at Edinburgh in connection with the International Exhibition. The series began on Tuesday, when Dr. Hopkinson occupied the chair. Dr. Walmsley read a paper on some of the principal features of the Exhibition, in which he referred particularly to the telegraph and electric light apparatus and gas-engines. Mr. A. R. Bennett read a paper on "Foreign Currents in Telegraph and Telephone Lines." He described experiments he had carried out with overhead wires, and pointed out their effect in wet weather. Mr. W. H. Preece said that the foreign currents found in electric wires were far more readily perceptible in telephone than in telegraph wires. The currents were due often to the swing of the wires, and greatly to the alternating system of generating electric light recently introduced. Mr. Bennett said that disturbances might be caused by the introduction of electric tramways. In the evening the members of the Society attended a *conversazione* given in their honour in the grand hall of the Exhibition. On Wednesday, when the chair was taken by Mr. W. H. Preece, a paper on "The Working Efficiency of Secondary Cells" was read. This paper, of which we hope to give some account, was the joint work of Messrs. W. E. Ayrton, C. G. Lamb, E. W. Smith, and M. W. Woods. On Thursday, Mr. Spagnoletti was in the chair, and Mr. A. R. Bennett read a paper on "Experiments on Radiometry." Some discussion followed, in which Dr. Walmsley, Mr. Stroh, Mr. Fairfax, and others took part.

AT the instance of a number of Magdeburg manufacturers, an electro-technical experimental station is about to be founded in that town, to afford to companies or private persons opportunity of experimenting as to the practicability and cost of various electrical arrangements, and of testing machines, apparatus, &c. The station will be arranged on the pattern of one already in existence at Munich, but expanded in several directions. Dr. M. Krieg, editor of the *Electrotechnical Echo*, will be at its head. Among other matters which will come under consideration, are the examination of arrangements for illumination, transmission of force, and metallurgical purposes, determination of the luminous power of arc and glow lamps, and of constants, such as intensity and tension of current, testing of carbon rods, of measuring-instruments, accumulators, primary batteries, &c., examination of conducting and insulating materials, lightning conductors, private telephone arrangements, and so on. Youths devoting themselves to electro-technical work will have opportunities of gaining thorough practical knowledge in the place.

THE death of Mr. John Ralfs, at Penzance, on the 14th inst., at the age of 83, removes one of the last survivors of a past generation of botanists. His "British Desmidieæ," published in 1848, remains to the present time unsurpassed in botanical literature for the beauty and accuracy of its coloured plates. As it was the first British work (except Hassall's "British Fresh-water Algæ," published three years earlier) which did any justice to this beautiful class of fresh-water organisms, so it remained the only one until the appearance of Dr. Cooke's "British Desmids" in 1887. Mr. Ralfs also contributed several papers on the Mosses, Fungi, and Algæ of his native county to the Transactions of local scientific Societies. Of a retiring disposition, and practising as a surgeon in Penzance, he was but little known personally to his fellow-workers. Within the last two years he was elected an Honorary Fellow of the Royal Microscopical Society.

MR. G. W. RAFTER has contributed to the Transactions of the American Society of Civil Engineers an interesting paper on freshwater Algæ, and their relation to the purity of public water-supplies. He finds that a number of Algæ may assist in rendering drinking-water unpotable, producing a nauseous or "fishy" smell, generally due to the decomposition of their mucilaginous envelope, or of the starch or oil contained in their cells. In addition to the well-known Fungus or Schizomycete *Beggiatoa*, which has the remarkable property of withdrawing sulphur from sulphates in solution, the following freshwater Algæ are especially deleterious when occurring in large masses:—*Cladophora*, *Vaucheria*, *Batrachospermum*, *Draparnaldia*, *Chætophora*, *Volvox*, *Eudorina*, *Pandorina*, *Hydrodictyon*, *Palmella*, *Crenothrix*, *Oscillaria*, and diatoms generally, especially *Meridion circulare*. Desmids appear to be usually innocuous.

THE British Vice-Consul at Los Angeles, in California, in his last Report, has some observations on the vine and orange pests in that region. The vine-disease now seriously menaces the existence of the viticultural industry in the vicinity of Los Angeles. At first it attacked chiefly the "mission" vines; now, other varieties of red vines are dying, and the white varieties are also suffering. The disease first appeared in its present dangerous form in the southern part of California, and destroyed many vineyards. Prof. Dowlen, an expert employed by the Viticultural Commission to ascertain its cause, and, if possible, discover a remedy, inclines to the opinion that it is due to a fungus. On the other hand, Mr. Wheeler, Chief Executive Officer of the Viticultural Commission, reports that he is fully convinced that the fungus found on the dead vines is not the prime cause of their decadence, and that it attacks them only when they have been weakened by other causes. As to the Icerya, or "white scale," which has ravaged the orange-groves, the Vice-Consul says that a year ago many of the principal orange-growers in the vicinity of Los Angeles had abandoned their efforts to exterminate this pest, concluding that their trees must die. Fortunately, it was learned that an Australian parasite, the *Vedolia cardinalis*, had exterminated the white scale in Australia. A colony of the bugs was imported, and placed on the trees in an orchard in Los Angeles; they multiplied so rapidly that in a few months the scale was entirely exterminated in the district; many trees, which a year ago were nearly dead, have revived and borne half a crop this season.

ARTIFICIAL musk is a recent chemical achievement. A process for its production has been patented in Germany, the inventor being Herr A. Bauer, of Gisparsleben, in the Erfurt

district. It is a familiar experience in organic chemistry, that on introduction of nitro groups (NO_2) into organic bodies, by action of nitric acid, a smell like that of musk is often noticed. In the present case, pure butyl-toluol is treated with a mixture of sulphuric and nitric acid, and the nitro-compound is purified by crystallization from alcohol, the yellowish-white crystals smelling strongly like musk. According to Dr. Paul (*Humboldt*), the smell is not perfectly pure, and it can be distinguished from that of musk by the perfumer, but not by the general public. Curiously, a 1 per cent. alcoholic solution has not the smell of musk; only after dilution with water does this come out, and the dilution may be carried far before the smell is lost; with 1 in 5000 it is still quite distinct. Certain properties of the new product seem to render it very useful in the perfuming of soap.

THE small toe in man has recently (we learn from *Humboldt*) been made a subject of study by Herr Pfitzner. It is well known that thumbs and great toes are two-jointed, and the other fingers and toes generally three-jointed. In many human skeletons, however, the small toe is found to be two-jointed, the middle and end phalanges being fused into one piece, though still distinguishable. This variety occurs in about 36 per cent. of cases, and, as a rule, in both toes simultaneously; and there are more instances among women (41·5 per cent.) than among men (31·0 per cent.). One naturally thinks here of shoe-pressure causing union of two bones originally separate. But it appears that in children, from birth to the seventh year, and in embryos from the fifth month, the fusion occurs about as often as in adults. Further, the material of examination was not from a class of people who wear tight shoes. Herr Pfitzner concludes that the small toe in man is in course of degeneration (*Rückbildung*), and that without apparent adaptation to external mechanical influences. Processes of reduction are also observed in the connected muscular system. The question arises, Has the tendency reached its limit, or have we merely the first act of a total degeneration of the fifth toe? The author inclines to the latter view, but desires an extension of these researches among peoples who do not wear shoes or sandals, or have only of late begun to wear them. In living persons, it is not difficult to determine, by stretching and bending, whether the small toe is two- or three-jointed; and in this way adequate data might be had for determining any percentage differences in occurrence of the old and the new form in different races; also for investigating the inheritance of acquired characters, members of several successive generations being examined.

DEFECTIVE sight is becoming more general in the United States, and blindness, particularly among the poor, shows a steady growth. So says the British Consul at Philadelphia, whose statements are advanced on the authority of oculists. Purulent ophthalmia of infancy is prevalent in charitable institutions, poor-houses, &c. The disease shows itself within a fortnight after birth. A recent investigation of the blind in the country almshouses and asylums of an adjoining State showed that one out of every five cases of blindness was due to ophthalmia, and that the cases could have been cured if they had been properly treated in time. The disease is said to be contagious, and few or no special precautions have been taken in any of the institutions to prevent its spreading. The increase of the blindness throughout the country has been so marked of late years—four times as great as the increase of population—that it has been made the subject of special investigation by the American Ophthalmological Society, the investigation including a study of the ophthalmia so prevalent in Egypt, to which the ophthalmia of infancy is closely akin.

A VERY odd result of rivalry between two tiger-snakes is recorded by Mr. D. Le Souef, Assistant Director of the Melbourne Zoological Gardens, in the May number of the *Victorian Naturalist*. One of the snakes was large, the other small. Not long ago both happened to fasten on the same mouse, one at each end. Neither would give way, and the larger snake not only swallowed the mouse, but also the smaller snake. In about ten minutes nothing was seen of the smaller snake but about two inches of its tail, and that disappeared next day.

IN the new quarterly statement of the Palestine Exploration Fund, Mr. Flinders Petrie gives a short report of his recent excavations at Tell Hesy, in Palestine. These have proved to be remarkably interesting. The remains of Tell Hesy consist of a mound which is formed of successive towns, one on the ruins of another, and an enclosure taking in an area to the south and west of it. The lowest wall of all—28 feet 8 inches thick, and formed of clay bricks, unburnt—is believed to be that of Lachish, the ancient Amorite city, erected probably 1500 years B.C. Phœnician pottery of about 1100 B.C. is found above its level. Later constructions are the supposed wall of Rehoboam, and remains of the fortifications made in the reigns of Asa, Jehoshaphat, Uzziah, Jotham, and Manasseh. The pottery discovered on the spot is very valuable. "We now know for certain," says Mr. Petrie, "the characteristics of Amorite pottery, of earlier Jewish and of later Jewish influenced by Greek trade, and we can trace the importation and the influence of Phœnician pottery. In future all the tells and ruins of the country will at once reveal their age by the potsherds which cover them."

M. P. MÉGNIN is engaged in an elaborate study of the varieties of dogs. He has published two volumes on the subject, and a third is to appear shortly. The author tries to give an account of the origin of the varieties at present known.

HERR A. HARTLEBEN, of Vienna, Pest, and Leipzig, has begun the publication, in "Lieferungen," of two works which promise to be very good and useful. They are "Das Luftmeer," by Prof. F. Umlauft, and "Physik und Chemie," by Dr. von Urbanitzky and Dr. S. Zeisel. Both works are illustrated. The former will present an exposition of the principles of meteorology and climatology; the latter is to contain a general account of physical and chemical phenomena in their relation to practical life.

DURING the last few months a fortnightly *Meteorological Bulletin* has been published at Madrid, by a person under the *nom de plume* "Noherlesoom," professing to give the principal features of the weather for the coming fortnight, illustrated by isobaric charts for special days. Some pages of text contain extracts from various orthodox works bearing upon weather prediction. The present state of the science does not warrant predictions of this nature, nor is it stated upon what principles they are made; yet the weather predicted for the first half of July corresponded in some respects to the very unseasonable conditions experienced during that period in this country.

THE new meteorological observatory of San José de Costarica is to be considered a welcome gain to science, seeing that (as Dr. Hann points out) between Mexico in 19° N. lat. and Rio de Janeiro and Cordoba in 22° and 35° S. lat., there has been no observatory of the first rank, either in Central or South America. Recent data from Prof. Pittier there, reveal a remarkable daily period of rainfall. Thus in the five months August to December, while only 1·5 inch of rain fell between midnight and midday, 35 inches, or more than twenty times as much, fell between midday and midnight. Comparing the hours, 6 to 11 a.m., with 2 to 7 p.m., the quantities are 0·3 in. and 27·6 in. Nearly the whole of the rainfall occurs within six hours (75½ per cent.). And the largest amount is towards sunset, not (as commonly supposed about the tropics) in the early hours of the afternoon.

WRITING on the subject of medicine in China, the *North China Herald* of Shanghai observes that medicine in China is very old. In the year 579 B.C. the moxa and acupunture were already practised by Chinese physicians, for it is in that year that this treatment is first mentioned in any book, Chinese or foreign. In addition to this there was the celebrated Pien-tsio, who some time during the period from the eighth century before Christ to the sixth performed remarkable cures by feeling the pulse first and basing his treatment upon the indications. On one occasion he was in attendance upon a prince who was in a state of unconsciousness for five days, and he depended on pulse-feeling for his knowledge of the patient's condition. The great books of Chinese medicine belonged to the age of the sages. They are the classics of Chinese medicine, and in them its theories and principles are enshrined. In these books we find such statements as that metal and water combine, in accord with the influence of Venus and Mars. The soul is spoken of as something distinct from though included in the body. Madness, fever, apoplexy, paralysis, cholera, are all described. The five elements are represented as revolving powers, and they correspond to the five planets in the heavens. The earth moves westward through space which surrounds it below as well as above and around. Ignorance of astrology is stated to be a cause of disease and death. Interlaced with the doctrine of the five elements is found the doctrine of the dual principles of darkness and light, each divided into greater and lesser. The veins and arteries are here described as canals originating in the skin, which, consequently, is that part at which all disease commences its invasion of the human frame. The possibility of the human subject securing immortality by Taoist methods is discussed, and the affirmative is believed. The "Soo wên," having in it these and other curious things, such as the rotundity of the earth and the doctrine of a universal and primæval vapour, and having a distinct tincture of the Mesopotamian astrology, constitutes in itself a convincing proof that China was receptive of Western knowledge to a large extent in the fifth, fourth, and third centuries before Christ. From that time during more than two thousand years China has been under the dominion of the philosophy of this book. The writer predicts that a history of Chinese medicine, being the result of the uninterrupted experience of two thousand five hundred years, in spite of its Babylonian theory, now exploded by modern discoveries, would prove deserving of high respect for its practical utility in many important ways.

THE Cambridge Local Lectures Syndicate held a Conference of Local Lecturers and Committees in the Senate House on July 9 and 10, the Vice-Chancellor, Dr. Butler, Master of Trinity College, presiding. The subjects discussed were: (1) the affiliation of lecture centres to the University; (2) the relations with the Education Department; (3) State aid for local lectures, a subject started at Oxford last year, and introduced on this occasion by the request of some of the centres, not as part of the programme of the Syndicate; (4) local finance; (5) work in rural districts; (6) district associations. The subjects were all of them actively discussed, "State aid" being referred back to the Committee which is working in the matter. The whole party, numbering about 180, lunched in the Hall of King's and dined in the Hall of Trinity, as guests of the Syndicate, and visited the Library, the Museums of Science, and the Fitzwilliam Museum, at each of which an expository address was delivered.

THE Syndicate have invited a limited number of their students in various parts of the Kingdom to spend the month of August in Cambridge, for the purpose of quiet and serious study. For some years, individual invitations of this kind have been given by persons interested in the work. The Syndicate have received favourable accounts of the work done and of the effect produced, and they are now making it part of their official business. They had contemplated from 30 to 40 students, but the number of those desirous of coming considerably exceeds that. The principle of the Syndicate is to give to the students opportunities which they could not have in the lecture centres, and on this account the ordinary subjects of local lectures are not included in the curriculum. The work is to last from August 5 to 30 inclusive. Newnham College will give a collegiate home to the women students, and Selwyn to the men, on very moderate terms. The mornings will be given to the science students, whose work will consist of courses of experimental demonstrations in the laboratories of chemistry, physics, geology, &c. The afternoons will be given to the art students, whose work will consist of series of lectures on Greek art, early English sculpture and inscriptions, early engraving, and architecture, all illustrated from the art collections and the buildings in Cambridge. Single lectures will be given, by leading residents in Cambridge, on subjects of which they have special knowledge, and this, no doubt, will be a feature of unusual interest and profit. The University Library, the Philosophical Library, and the Library of Art and Archæology, will all be open to the students by special arrangement for reading and study. Special lectures will be given on King's Chapel and Ely Cathedral, and the manuscript and other treasures of some of the College libraries will be shown and described in detail. Visits will be paid to the Observatory by day, for the inspection of the astronomical instruments, and Prof. Adams or his representative will receive small parties of the students at night. It is proposed to give to those who go satisfactorily through the regular course of study some record of what they have done. Several of the lecture centres have given scholarships of £10 to their best students to enable them to go to Cambridge, and the Syndicate are meeting all prizes of this kind by a remission of the small lecture fee. The advantage of working in small parties of 10 or 12 at such subjects as those indicated, and under such circumstances, can scarcely be exaggerated. The determination of the Syndicate is that the whole course of study shall be serious and quiet, but social amenities will not be disregarded.

THE Report of the Cambridge Local Lectures Syndicate, recently issued, is unusually encouraging. The number of students and of courses of lectures is larger than ever, and the proportion of serious students to the whole number attending the lectures shows a remarkable increase. It is easy to get a large number of people to come to popular lectures, but to make people who come to lectures into serious students is a different matter. Nearly half of the whole number of 11,500 students have attended not the lecture only, but also the "class" for more detailed work by question and answer which always precedes or follows the lecture in the Cambridge system. More than a fifth part of the whole have written papers weekly for the lecturer, and the examinations at the end of the respective courses have been attended by nearly one in six. This is an interesting record of solid work done. A specially satisfactory feature of the year's work has been the manner in which the centres have supported the Syndicate in keeping up the lectures in each course to the full number of twelve, which is an integral part of the Cambridge system. Of 125 courses only five have been "half-courses" of six lectures, given under special circumstances and without the privilege of an examination. Thus the total number of lectures given has been about 1470, and the number of attendances at lectures not far off 140,000.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus* ♀ ♀) from India, presented by Captain C. Taylor; a Hawfinch (*Coccothraustes vulgaris*), British, presented by Mr. L. C.

Wharton; a Snow Bunting (*Plectrophanes nivalis*), European presented by Mr. J. Young, F.Z.S.; a Common Boa (*Boa constrictor*) from Venezuela, presented by Mr. R. J. Money; a White-thighed Colobus (*Colobus vellerosus* ♂) from West Africa, a Cape Ratel (*Mellivora capensis* ♂) from South Africa, an Arctic Fox (*Canis lagopus* ♀) from the Arctic Regions; four Spoonbills (*Platalea leucorodia*), European, a Short-toed Lark (*Calendrella brachydactyla* ♂) from Algeria, purchased; four Australian Wild Ducks (*Anas superciliosa*), two Slender Ducks (*Anas gibberifrons*), eight Chilian Pintails (*Dafila spinicauda*), six Summer Ducks (*Æx sponsa*), four Mandarin Ducks (*Æx galericulata*), two Red-crested Pochards (*Fuligula rufina*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on July 24 = 18h. 10m. 17s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4390	—	—	18 6 45	+ 6 49
(2) G.C. 4403	—	—	18 14 17	− 16 13
(3) D.M. + 43° 2890 ...	8	Reddish-yellow.	18 3 29	+43 26
(4) η Serpentis	3	Yellow.	18 15 36	− 2 56
(5) γ Ophiuchi	3	White.	17 42 16	+ 2 45
(6) D.M. + 36° 3243 ...	8	Red.	18 39 0	+36 50

Remarks.

(1) This small bright nebula was thought by W. Struve to be one of the most curious objects in the heavens. The G.C. description is: "A planetary nebula; very bright; very small; round; a little hazy." According to D'Arrest, its diameter is about 7″. The observations of Dr. Huggins and Captain Herschel show that the spectrum consists of the three chief nebula lines, and a faint continuous spectrum. Dr. Huggins also notes that "the lines are exceedingly sharp and well-defined." This latter observation requires confirmation, and the spectrum should also be examined for other lines, as we know that a greater number of lines are seen in other nebulæ of the same class.

(2) This is the so-called "Horse-shoe Nebula," which is thus described by Herschel: "A very remarkable object; bright; extremely large; extremely irregular figure; 2-hooked." The spectrum has been observed both by Dr. Huggins and Captain Herschel. The former noted in 1866 that the line near λ 500 was visible, in addition to a faint continuous spectrum, and added: "When the slit was made as narrow as the intensity of the light would permit, this bright line was not so well defined as the corresponding line in some of the other nebulæ under similar conditions of slit, but remained nebulous at the edges." It will be seen that this observation gives the chief line a very different character to the preceding one (4390), and it is very desirable that the discrepancy should be cleared up, especially as Dr. Huggins has recently stated that the line is always seen sharp and well defined, although there is no evidence to show that he has reobserved the nebulæ in which he formerly recorded it as ill defined. It is important that both nebulæ should be examined as nearly as possible at the same time with the same instrumental conditions. Captain Herschel simply writes: "Bright object; bright lines."

(3) The spectrum of this star is one of great interest in connection with the view that stars of Group II. are similar in constitution to comets. Dunér states that, notwithstanding the small magnitude of the star the bands are very well seen even in the ultra blue, and that they are so wide and dark that the spectrum is totally discontinuous, especially in the blue-green and the blue. Now it seems pretty evident that all the light referred to in the blue in a faint star like this cannot be due simply to continuous spectrum, and it is therefore probably due to the radiation of some substance. This substance is probably carbon, giving a series of bright flutings in the blue-green and blue, and giving rise to apparent dark bands, which are in all probability simply the dark spaces between the bright flutings. The measurements made by Dunér and Vogel of the bands in other stars show close coincidences with the carbon flutings, but the question can only be finally decided by direct comparisons. If the existence of the carbon flutings be confirmed, then we must conclude that stars of Group II. and comets showing the same series of flutings are identical in constitution.

(4 and 5) These are stars of the solar type and of Group IV. respectively, and the usual more detailed observations are required in each case.

(6) The observations of Secchi and Dunér show that the spectrum of this star is a well-marked one of Group VI.; but the only details observed were three "zones" separated by two strong dark bands. Further details and deviations from the regular type should be looked for. A. FOWLER.

NICE OBSERVATORY.—The third volume of the "Annales de l'Observatoire de Nice" contains a new map of the solar spectrum by the late M. L. Thollon, the whole of the theory of the minor planet Vesta by M. Perrotin, the Director of the Observatory, and numerous observations of comets and planets made by M. Charlois.

The part of the spectrum mapped by M. Thollon extends from A to *b*, and is contained on seventeen beautifully engraved plates, each having two horizons 32 cm. long. The whole length is thus a little over ten metres, and the number of lines contained in it is about 3200, of which 2090 are said to have a solar origin, 866 are purely telluric, and 246 have a mixed origin—that is to say, they result from the superposition of solar and telluric lines.

Each of the 33 horizons is divided into millimetres, from 0 to 320, hence the lines can easily be read off to $\frac{1}{10}$ of a division. Thollon intended at the beginning of his work to express the position of the lines on a scale of wave-lengths, and this would doubtless have facilitated their identification to a considerable extent; but the method of relative measurement which he adopted was more accurate than the absolute measures made by Ångström, and he found that to use a wave-length scale it would be necessary to alter a number of accepted places of lines or to alter his measured intervals. It is rather unfortunate that such should be the case, for ready reference to the lines and comparisons of them with those mapped by other observers are rendered somewhat difficult. Beneath each scale are four horizons on which are respectively represented: (1) the appearance of the lines when the sun is 80° from the zenith and the air is dry; (2) the appearance of the lines when the sun is 60° from the zenith and the air is very moist; (3) the appearance of the lines when the sun is 60° from the zenith and the air is very dry; (4) the lines of solar origin—that is, those that would be observed from outside our atmosphere. The width of the lines was determined for each of the four horizons, and intensities are expressed from 1 to 10, 1 indicating the weakest and 10 the strongest lines. The values for each line are given in the text relating to the maps. Another horizon gives the position of iron lines, but this is incomplete in some of the maps owing to M. Thollon's death.

The theory of Vesta, by M. Perrotin, is in continuation of that published in the first volume of "Annales de l'Observatoire de Toulouse, 1880," and deals with the algebraical expressions of the perturbations produced on its elements by different planets.

ENLARGEMENT OF PHOTOGRAPHS OF STELLAR SPECTRA.—The enlargement of all the photographs of stellar spectra taken under Prof. Pickering's direction at the Henry Draper Memorial observatories is made by means of a cylindrical lens, and the result of the adoption of this method is well known. Dr. Scheiner, of Potsdam Observatory (*Astronomische Nachrichten*, No. 2969), has obtained even better results by fixing the negative lengthways in a frame which has a to-and-fro movement. The motion causes the width of the lines to be increased on the plate being exposed, in a manner similar to the increase that takes place when a cylindrical lens is inserted between it and the negative. The advantage of the arrangement over that of Prof. Pickering lies in the fact that the diminution of the intensity of the lines in the process of enlargement is much less.

The method now described by Dr. Scheiner has been used successfully at South Kensington for some time.

THE SCIENTIFIC PRINCIPLES INVOLVED IN MAKING BIG GUNS.

I.

STEAMSHIPS are now called *boats*, and the largest cannon are called *guns*, according to a process in language which philologists have explained; but while steamships have increased in size and complication, the gun, however big, satisfies the Hibernian definition of a cylindrical hole with metal placed round it; and the most difficult problem of the gun-maker is to dispose the metal in the most efficient manner, hampered as he is by the limitations of the metallurgical art.

The difficulties increase with the size of the gun, according to the well-known law of Mechanical Similitude.

Geometrical Similitude is independent of scale; a geometrical theorem is true, however large the figure may be drawn; but the laws of Mechanical Similitude are complicated, when we notice the differences between a simple girder and the Forth Bridge, or between the anatomy of large and small animals.

As an example of mechanical similitude, consider what sort of a steamship would be required to reduce the voyage to America from six to five days. The present steamers crossing in six days have a speed of 20 knots, and displacement of 10,000 tons, and the indicated horse-power is close on 20,000. To cross in five days the speed would have to be increased 20 per cent., to 24 knots; and now if we apply Froude's law that, at corresponding speeds as the sixth root of the displacements, the resistances are as the displacements, we shall find that the steamer would have to be of 30,000 tons, and of 65,000 horse-power, thus exceeding even the *Great Eastern's* dimensions.

With given material, say steel, the strongest with which we are familiar, a limit of size is soon reached at which the structure falls to pieces almost of its own weight; and recent experience with the heaviest artillery seems to show that we are nearing this limit.

The larger the gun or structure, then, the greater the necessity for careful and scientific design and proportion. It is proposed to give here a sketch of the fundamental principles which guide the gun-maker, and which he applies to secure the safety of the gun under the greatest pressure it can ever be called upon to sustain.

While reaping almost all the glory of success, the gun-maker cannot risk the disgrace of a failure; on the other hand, the carriage-maker can work with a small margin of safety, as ample warning would be given of any failure, and breakage is easily repaired; but the failure of a gun may be so disastrous that it must be avoided at all cost, so that the gun-maker never allows himself to work very close to the limits which his theory allows.

At the present time the design and employment at sea or in forts of such monsters as our 110-ton or Krupp's 135-ton guns is severely criticized and condemned in certain circles; but it is a maxim in artillery that one big gun is worth much more than its equivalent weight in smaller guns; and for naval engagements a few line-of-battle ships armed with the heaviest artillery are invincible, if properly flanked and protected by the light cavalry of frigates.

So, too, with steamships; the largest and fastest always fill with passengers, and by making rapid passages, and therefore more in a given time, are found to be more profitable in spite of their great initial cost and expense of working.

The size of the gun is settled by the thickness of armour it is required to attack; the calibre increasing practically as the thickness to be pierced, but the weight of the gun mounting up as the cube of the calibre. Thus if an 8-inch gun weighing 13 tons can pierce 12 inches of armour, a 16-inch gun is required to pierce 24 inches, and the 16-inch gun will weigh 104 tons.

PART I.—THE STRESSES IN A GUN.

(1) The theory of gun-making begins with the investigation of the stresses set up in a thick metal cylinder, due to steady pressures, applied either at the interior, or exterior, or at both cylindrical surfaces.

So far, the dynamical phenomena which arise from the propagation and reflexion of radial vibrations are beyond our powers of useful analysis; so that we restrict ourselves to the investigation of the elastical problem of the thick cylinder of elastic material, subject to given internal and external pressures, applied steadily, as in the case of a tube tested under hydraulic pressure.

Fig. 1 is drawn representing the stresses set up in a cylinder or tube B, by an internal pressure p_i; we denote by r_i and r_o the inner and outer radii, the suffixes i and o denoting *inside* and *outside*; and then r can be used to denote any intermediate radius.

The stress at any point at a distance r from the axis will consist of a radial pressure, p, and a circumferential tension, t; the radial pressure p decreasing from p_i at the inner radius r_i to zero at the outer radius r_o, the atmospheric pressure not being taken into account; while the circumferential tension t at the same time diminishes from t_i to t_o.

The British units employed in practical measurements with guns are the inch and the ton; so that r being measured in inches, p and t are measured in tons per square inch.

(2) To determine the state of stress at any point of the cylinder, we suppose it divided by a diametral plane $r_o r_i \mathrm{O} r_i r_o$; and the equilibrium of an inch length of either half is considered.

The stresses p and t being represented graphically by the ordinates of the curves $p_i p p_o$, $t_i t t_o$, the equilibrium of either half of the cylinder requires that the area of the circumferential tension-curve $r_i t_i t_o r_o$ and its counterpart should be equal to the area of the rectangle $\mathrm{O}p_i$, and its counterpart, these latter representing the thrust due to the pressure p_i on the half cylinder.

Then, denoting the area $r_i t_i t_o r_o$ by Q, and calling it the resistance of the section $r_i r_o$,

$$Q = p_i r_i \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1).$$

If we divide the resistance Q by the thickness of the cylinder $r_o - r_i$, we obtain the *average* circumferential tension in the material; and when the cylinder is thin, the maximum circumferential tension t_i and the average tension $Q/(r_o - r_i)$ will not be appreciably different; so that a knowledge of the average circumferential tension will be sufficient for practical purposes in such cases as, for instance, of the cylindrical shell of a boiler; and we have thus the elementary formula ordinarily employed in the design of boilers.

But when, as in a gun or hydraulic press, the thickness has to be made considerable, we must have the means of determining the *maximum* tension t_i, and of contriving that t_i shall not exceed a certain proof limit suitable for the material.

(3) Now, just as the equilibrum of either half of the cylinder requires that the area $r_i t_i t_o r_o = p_i r_i$, so the equilibrium of either half of a part of the cylinder bounded internally by the radius r_i, and externally by any radius r, requires that the area $r_i t_i t r$ should equal the rectangle $\mathrm{O}p_i$ minus the rectangle $\mathrm{O}p$; or, in the notation of the Integral Calculus—

$$\int_{r_i}^{r} t dr = p_i r_i - pr \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

The first attempt at a solution of these equations (1) and (2) is due to Peter Barlow, when called upon to calculate the strength of the cylinder of the Bramah hydraulic press, in a paper read before the Society of Civil Engineers in February 1825, and published in the *Edinburgh Journal of Science*, and in the Trans. I.C.E., vol. i. 1836.

(4) Barlow assumed that under an internal pressure the metal is compressed radially as much as it is stretched circumferentially, so that the cubical compression of the metal is zero, and he is justified therefore in putting $p = t$ in the material of the cylinder.

Then equation (2) becomes

$$\int_{r_i}^{r} p dr = p_i r_i - pr;$$

so that, differentiating with respect to r,

$$p = -d(pr)/dr, \text{ or } dp/p + 2dr/r = 0;$$

and integrating again with respect to r,

$$\log p + \log r^2. = \text{constant},$$

or

$$pr^2 = a, \text{ a constant}; \ p = t = ar^{-2} \quad . \quad . \quad . \quad . \quad (3);$$

so that p and t, if equal, vary inversely as the square of the distance from the axis.

Thus, a cylindrical tube under internal and external pressures which are inversely as the squares of the internal and external radii respectively, will, according to Barlow's law, have at any point a radial pressure and an equal circumferential tension, also inversely as the square of the distance from the axis.

When the thickness of the cylinder is considerable, compared with the bore, this solution of Barlow will give a very fair indication of the true result.

(5) But Rankine showed ("Applied Mechanics," § 273) that, by superposing the state of hydrostatic stress produced by equal internal and external pressures, we obtain the algebraical solution of the most general case where the internal and external applied pressures are arbitrary.

For if we suppose the state of stress in the cylinder is a hydrostatic stress, composed of a radial pressure p, and an equal circumferential pressure $-t$, then equation (2) becomes—

$$\int_{r_i}^{r} p\,dr = pr - p_i r_i;$$

and differentiating with respect to r,

$$p = d(pr)/dr, \text{ or } dp/dr = 0;$$

so that

$$p = b, \text{ a constant; and then } t = -b \quad . \quad . \quad . \quad (4).$$

(6) The superposition of this state of stress on Barlow's state of stress gives—

$$p = ar^{-2} + b, \qquad t = ar^{-2} - b \quad . \quad . \quad . \quad . \quad (5),$$

or

$$(p + t)r^2 = 2a, \qquad p - t = 2b;$$

values which will be found to verify equation (2); and now the constants a and b are determined for arbitrarily applied internal and external pressures p_i and p_o by the equations

$$p_i = ar_i^{-2} + b, \qquad p_o = ar_o^{-2} + b;$$

so that

$$a = \frac{p_i - p_o}{r_i^{-2} - r_o^{-2}} = \frac{(p_i - p_o)\,r_i^2 r_o^2}{r_o^2 - r_i^2};$$

$$b = \frac{p_o r_o^2 - p_i r_i^2}{r_o^2 - r_i^2} = \frac{p_o r_i^{-2} - p_i r_o^{-2}}{r_i^{-2} - r_o^{-2}}.$$

These results were first obtained by Lamé and Hart (the late Sir Andrew Searle Hart, of Dublin), but in a much more complicated manner. Lamé's solution was given in his "Leçons sur la théorie mathématique de l'élasticité des corps solides"; while Hart's treatment of the question will be found in Note W to Robert Mallet's "Physical Conditions involved in the Construction of Artillery" (1856). An investigation of the same problem by Maxwell, when about eighteen years old, in the Trans. R. S. Edin., vol. xx. 1850, has been generally overlooked.

Rankine's treatment analyzes the mechanical signification of the separate terms of the solution, and obtains them by simple reasoning from the state of stress, without an appeal to the laws of elasticity and the consequent state of strain.

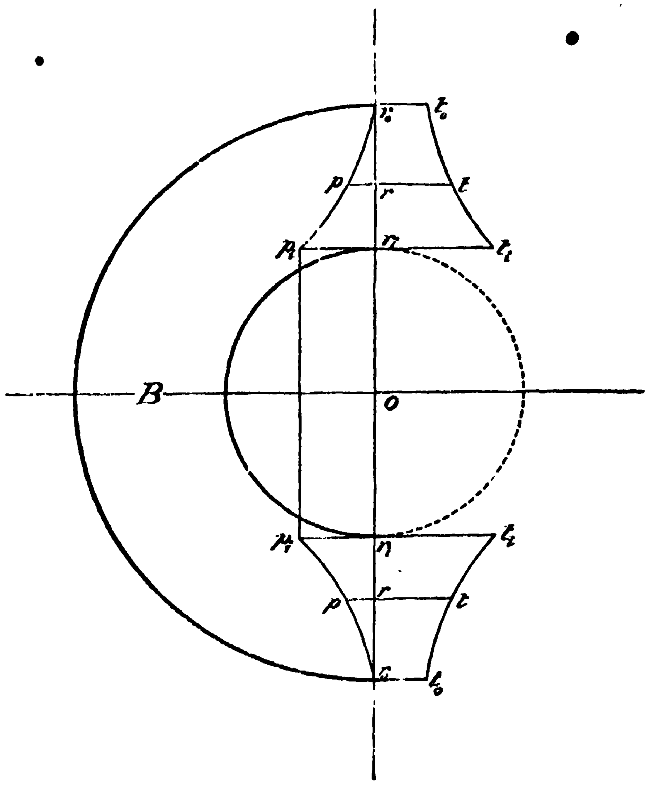

FIG. 1.

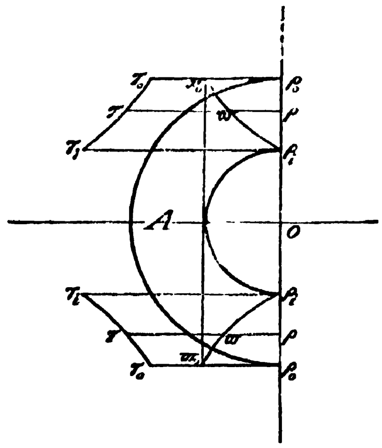

FIG. 2.

(7) Putting $p_i r_i^2 = p_o r_o^2$ makes $b = 0$, and gives the particular case considered first by Barlow; and putting $p_i = p_o$ makes $a = 0$, and gives the additional particular case of uniform hydrostatic stress invented by Rankine.

But, in the general case, a and b may have any values, positive or negative, according to the relations between p_i and p_o, r_i and r_o.

Thus, as in Fig. 1, with $p_o = 0$, we find—

$$a = \frac{p_i}{r_i^{-2} - r_o^{-2}}, \quad b = \frac{-p_i r_o^{-2}}{r_i^{-2} - r_o^{-2}};$$

and then

$$p = ar^{-2} + b = p_i\frac{r^{-2} - r_o^{-2}}{r_i^{-2} - r_o^{-2}}; \quad . \quad . \quad . \quad . \quad . \quad (6)$$

$$t = ar^{-2} - b = p_i\frac{r^{-2} + r_o^{-2}}{r_i^{-2} - r_o^{-2}}; \quad . \quad . \quad . \quad . \quad . \quad (7)$$

$$t_i = p_i\frac{r_i^{-2} + r_o^{-2}}{r_i^{-2} - r_o^{-2}} = p_i\frac{r_o^2 + r_i^2}{r_o^2 - r_i^2}; \quad . \quad . \quad . \quad . \quad (8)$$

$$t_o = p_i\frac{2r_o^{-2}}{r_i^{-2} - r_o^{-2}} = p_i\frac{2r_i^2}{r_o^2 - r_i^2} \quad . \quad . \quad . \quad . \quad . \quad (9)$$

(8) Now using t to denote the *average* value of the circumferential tension, so that

$$t = p_i r_i/(r_o - r_i),$$

then

$$\frac{t_i}{t} = \frac{r_o^2 + r_i^2}{r_i(r_o + r_i)}, \quad \frac{t_i - t}{t} = \frac{r_o}{r_i}\,\frac{r_o - r_i}{r_o + r_i} \quad . \quad . \quad (10)$$

thus showing that the maximum tension t_i may exceed the average tension t by a considerable amount; and it is this *maximum* tension t_i which must be carefully watched and kept down below a certain working value; so that, with given t_i, the maximum allowable pressure in the tube is given by

$$p_i = t_i\frac{r_o^2 - r_i^2}{r_o^2 + r_i^2}.$$

This is the formula now used in the design of a hydraulic press, or of a thick tube, of bore $2r_i$, to stand an internal pressure p_i; t_i being fixed by the strength of the material, and then r_o being calculated.

We notice that p_i is always less than t_i, so that a tube, how-

ever thick, cannot stand, if unsupported, an internal pressure greater than the working tenacity of the material.

But, as the pressures in gunnery often exceed the tenacity of any known material, the requisite strength must be provided by an initial compression of the tube due to shrinking on one or more cylindrical jackets.

(9) Fig. 2 is drawn representing graphically the state of stress set up in a tube A by an external applied pressure ϖ_o, as in the tube or flue of a boiler by the external pressure of the water, or in the internal tube of a gun by the shrinkage pressure of the outside jacket.

Denote by ρ_i and ρ_o the inner and outer radii of the tube A, and by ρ any intermediate radius.

The stress at any point of the tube will now consist of a radial pressure ϖ, and of a circumferential *pressure* τ, represented by the ordinates of the curves $\varpi_o\varpi\varpi_i$, $\tau_o\tau\tau_i$; and dividing the tube by a diametral plane $\rho_o\rho_i O\rho_i\rho_o$, and considering the equilibrium of inch length of either half, we shall find as before that the area $\rho_i\tau_i\tau_o\rho_o$ = the rectangle $O\varpi_o = \varpi_o\rho_o$; while considering the equilibrium of any coaxial cylindrical portion, bounded by the radii ρ_o and ρ, then the area $\rho\tau\tau_o\rho_o$ = rectangle $O\varpi_o$ − rectangle $O\varpi$; or, in the notation of the Integral Calculus—

$$\int_{\rho}^{\rho_o} \tau d\rho = \varpi_o\rho_o - \varpi\rho \; ; \quad \ldots \ldots \quad (11)$$

leading, by differentiation with respect to ρ, to

$$\tau = -d(\varpi\rho)/d\rho \; ; \quad \ldots \ldots \quad (11^*)$$

the general solution of which can, as before, be exhibited in the form—

$$\varpi = \beta + \alpha\rho^{-2}, \quad \tau = \beta - \alpha\rho^{-2}, \quad \ldots \quad (12)$$

or

$$(\varpi - \tau)\rho^2 = 2\alpha, \quad \varpi + \tau = 2\beta,$$

where α and β are arbitrary constants, determined from the values of the arbitrary pressures applied to the interior and exterior surfaces.

(10) Now with $\varpi_i = 0$,

$$0 = \beta + \alpha\rho_i^{-2}, \quad \varpi_o = \beta + \alpha\rho_o^{-2};$$

so that

$$\alpha = \frac{-\varpi_o}{\rho_i^{-2} - \rho_o^{-2}}, \quad \beta = \frac{\varpi_o\rho_i^{-2}}{\rho_i^{-2} - \rho_o^{-2}};$$

and then

$$\varpi = \beta + \alpha\rho^{-2} = \varpi_o \frac{\rho_i^{-2} - \rho^{-2}}{\rho_i^{-2} - \rho_o^{-2}}, \quad \ldots \quad (13)$$

$$\tau = \beta - \alpha\rho^{-2} = \varpi_o \frac{\rho_i^{-2} + \rho^{-2}}{\rho_i^{-2} - \rho_o^{-2}}, \quad \ldots \quad (14)$$

$$\tau_o = \varpi_o \frac{\rho_i^{-2} + \rho_o^{-2}}{\rho_i^{-2} - \rho_o^{-2}} = \varpi_o \frac{\rho_o^2 + \rho_i^2}{\rho_o^2 - \rho_i^2}, \quad \ldots \quad (15)$$

$$\tau_i = \varpi_o \frac{2\rho_i^{-2}}{\rho_i^{-2} - \rho_o^{-2}} = \varpi_o \frac{2\rho_o^2}{\rho_o^2 - \rho_i^2}. \quad \ldots \quad (16)$$

Given, then, τ_i the maximum allowable crushing pressure of the material, then

$$\varpi_o = \tau_o(\rho_o^2 - \rho_i^2)/2\rho_o^2 = \tfrac{1}{2}\tau_o(1 - \rho_i^2/\rho_o^2) \quad \ldots \quad (17)$$

is the maximum allowable external pressure on the tube.

(11) If we make $\rho_o = r_i$ and $\varpi_o = p_i$, the tube A of Fig. 2 may be supposed to be gripped by the cylinder B of Fig. 1, of which only the upper halves need now be shown, as in Fig. 3; and now Fig. 3 will represent the cross-section of a tube, A, over which a jacket, B, has been shrunk, as at the breech end of an ordinary field-gun, and will represent graphically the stresses set up when the pressure, $\varpi_o = p_i$, at the common surface, is supposed known; these are called the *initial stresses*, or stresses of repose; the internal pressure at the radius ρ_i and the external pressure at the radius r_o being zero, as the atmospheric pressure is insensible in our calculations.

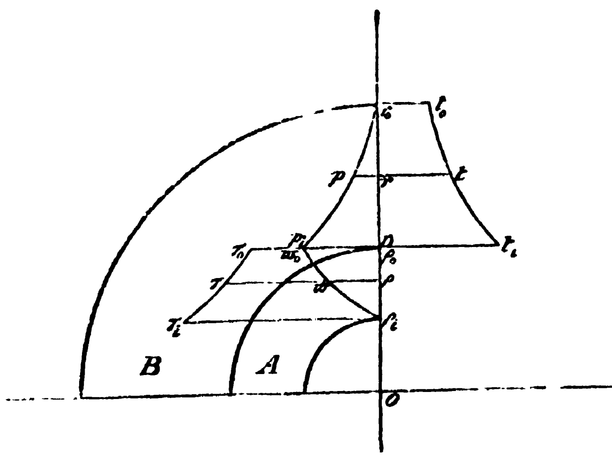

FIG. 3.

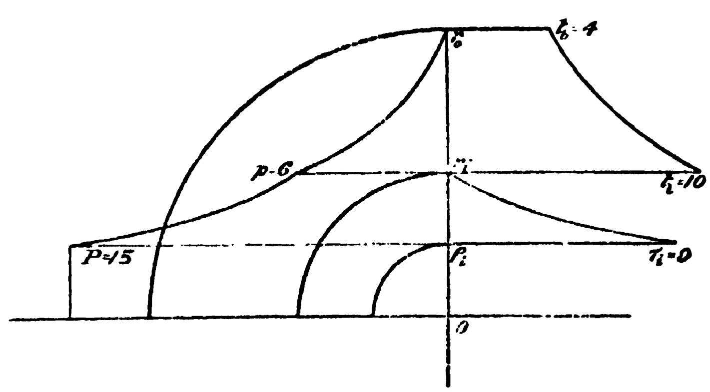

FIG. 4.

In Fig. 3 we notice that the total pull resistance across the section $r_o r_i$, represented by the area $r_o t_o t_i r_i$, is equal to the total thrust resistance of the section $\rho_o\rho_i$, represented by the area $\rho_o\tau_o\tau_i\rho_i$, and each of these is equal to the resultant pressure thrust represented by the area of the rectangle Op_i.

(12) Now, suppose a pressure P (say 15 tons on the square inch) is applied at the interior of the tube, either by the steady pressure of water, as in a hydraulic press, or by the momentary pressure of gunpowder, as in the bore of a gun.

We suppose that the additional stresses due to this pressure, P, which we shall call the *powder stresses*, are the same as those which would be set up in a homogeneous cylinder of internal radius ρ_i, and external radius r_o, by a steady pressure, P; and these powder stresses will therefore, by what precedes, in equations (6), (7), (8) (Fig. 1), at a distance r from the axis, consist of a radial pressure—

$$P \frac{r^{-2} - r_o^{-2}}{\rho_i^{-2} - r_o^{-2}}, \quad \ldots \ldots \quad (18)$$

and a circumferential tension—

$$P \frac{r^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}}, \quad \ldots \ldots \quad (19)$$

having a maximum value at the bore of

$$T = P \frac{\rho_i^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}}.$$

We must superpose these powder stresses on the initial stresses of the compound cylinder to obtain the stresses when the cylinder is used as a gun (or hydraulic press); these are called the *firing stresses*, and they are exhibited graphically in Fig. 4.

(13) We now see the reason for setting up initial stresses in the gun by shrinking a jacket over the interior tube.

For the maximum circumferential tension at the bore on firing is reduced by the initial stresses from

$$T = P\frac{\rho_i^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}} \text{ to } P\frac{\rho_i^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}} - \varpi_o \frac{2\rho_i^{-2}}{\rho_i^{-2} - \rho_o^{-2}}, \quad (20)$$

while at the interior of the jacket the circumferential tension is altered from

$$P\frac{r_i^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}} \text{ to } P\frac{r_i^{-2} + r_o^{-2}}{\rho_i^{-2} - r_o^{-2}} + p_i\frac{r_i^{-2} + r_o^{-2}}{r_i^{-2} - r_o^{-2}}. \quad \ldots (21)$$

The maximum stresses in the gun are thereby equalized to a great extent, and material can be economized.

(14) Thus, with $\rho_i/\rho_o = r_i/r_o = \frac{1}{2}$, and $P = 15$, the powder stresses are given by circumferential tensions—

$$T = \tau_i = 17, \qquad t_i = 5;$$

so that, with a shrinkage pressure $\varpi_o = p_i = 3$, the principal firing stresses are given by circumferential tensions—

$$\tau_i = 17 - 8 = 9, \text{ a great reduction on } 17,$$
$$t_i = 5 + 5 = 10,$$

while

$$\tau_o = 5 - 5 = 0.$$
$$t_o = 2 + 2 = 4.$$

We need not consider the radial pressures for practical purposes.

To equalize these maximum tensions, $\tau_i = 9$ and $t_i = 10$, the tube might be made slightly thicker and the jacket thinner, or else the shrinkage pressure ϖ_o or p_i slightly diminished, keeping to the same bore and external diameter.

(15) We have thus shown how the initial stress, the powder stress, and the firing stress at any point of a gun composed of a tube and a single jacket is found, and exhibited graphically in Figs. 3 and 4.

The curves in the figure are seen to be all similar to a curve whose equation is of the form $y = ax^{-2}$, now called the Barlow curve.

When the gun is built up of three or more concentric cylinders, the method of procedure is the same; the initial pressure between the cylinders may be supposed known from the amount of shrinkage given in the manufacture; and now, taking any intermediate cylinder of the gun under initial pressures p_i and p_o at the internal and external surfaces, of radii r_i and r_o, we erect ordinates to represent p_i and p_o, and draw the Barlow curve joining their ends.

The Barlow curve representing the circumferential tension or pressure will always appear as an equal reflection of the pressure curve, the position being assigned so as to make the area of the circumferential *tension* curve equal to $p_i r_i - p_o r_o$; and it may happen that this area may vanish or become negative, showing that some or all of the initial circumferential tensions are really pressures.

(16) But practically the gun-maker reverses this procedure; with him it is the maximum circumferential firing tension t_i of a tube or hoop which is limited by the strength of the metal; so that, starting with these t_i's, as given, he calculates the pressures between the successive coils of the gun, proceeding inwards; and finally determines the maximum allowable powder pressure in the interior of the bore.

Afterwards he subtracts the powder stresses from these firing stresses, and thus obtains the initial stresses in the gun; and then from these initial stresses he calculates the amount of shrinkage to be given to the coils or hoops to obtain the requisite state of initial stress. But we shall show subsequently that the requisite amount of shrinkage is given just as simply from the firing stresses as from the initial stresses; so that henceforth we need only determine the firing stresses.

(17) Then Fig. 5 represents the maximum allowable firing stress over the powder-chamber of the American 8-inch gun, shown in cross-section, as composed of an inner tube, A, over which a jacket, B, and two hoops, C and D, have been shrunk on.

In practice, the maximum allowable tension in the jacket and hoops is restricted to 18 tons per square inch, but in the inner tube to 15 tons per square inch, so as to allow for erosion of the bore, the weakening due to the rifling grooves, and the possible failure of the tube.

(18) In the notation of the "Text-book of Gunnery," 1887, by Major Mackinlay, R.A., supposing there are n cylinders in the cross-section of the gun, the successive radii of the cylindrical

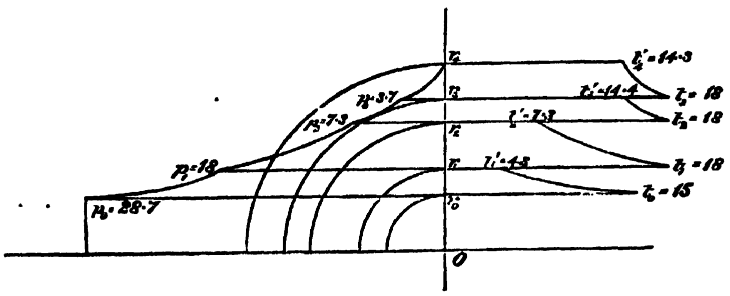

FIG. 5.

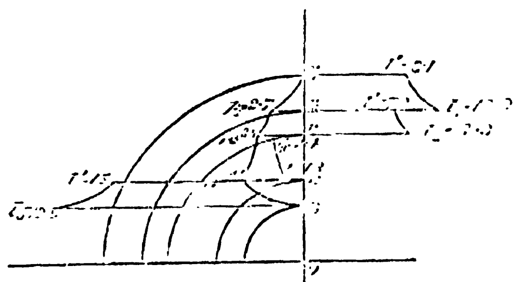

FIG. 6.

surfaces, beginning from the outside, are denoted in inches by $r_n, r_{n-1}, \ldots, r_2, r_1, r_0$; and the firing pressures at the surfaces of separation are denoted by $p_{n-1}, \ldots, p_2, p_1$; and p_0 finally denotes the powder pressure at the radius r_0 of the bore.

We notice that there is no sudden change in the value of the radial pressure; but that the circumferential tension, t, changes suddenly from one cylinder to the next.

As we are concerned principally with the *maximum* tensions, which occur practically at the inner surface of a cylinder, we denote them, proceeding inwards, by $t_{n-1}, t_{n-2}, \ldots t_2, t_1, t_0$; and we shall suppose them to change suddenly to $t'_{n-1}, t'_{n-2}, \ldots t'_2, t'_1$, in proceeding inwards to the next cylinder.

(19) Starting from the outside cylinder, the stress formulas give, since $p_n = 0$,

$$p_{n-1} = ar_{n-1}^{-2} + b, \qquad 0 = ar_n^{-2} + b,$$

while

$$t_{n-1} = ar_{n-1}^{-2} - b, \qquad t'_n = ar_n^{-2} - b;$$

so that

$$p_{n-1} = a\left(r_{n-1}^{-2} - r_n^{-2}\right),$$

$$t_{n-1} = a\left(r_{n-1}^{-2} + r_n^{-2}\right),$$

or

$$p_{n-1} = \frac{r_{n-1}^{-2} - r_n^{-2}}{r_{n-1}^{-2} + r_n^{-2}} \cdot t_{n-1}, \quad \ldots \ldots \quad (22)$$

giving p_{n-1} when t_{n-1} is assigned by its maximum allowable value.

Also

$$t_{n-1} - t'_n = p_{n-1}, \quad \ldots \ldots \quad (23)$$

giving t'_n, if required for the diagram.

Proceeding inwards to the next cylinder, we have (with different values of a and b)—

$$p_{n-2} = ar_{n-2}^{-2} + b, \qquad p_{n-1} = ar_{n-1}^{-2} + b,$$

$$t_{n-2} = ar_{n-2}^{-2} - b, \qquad t'_{n-1} = ar_{n-1}^{-2} - b;$$

so that, eliminating the a and b, first b and then a,

$$p_{n-2} - p_{n-1} = a\left(r_{n-2}^{-2} - r_{n-1}^{-2}\right),$$

$$t_{n-2} + p_{n-1} = a\left(r_{n-2}^{-2} + r_{n-1}^{-2}\right),$$

and therefore, by division,

$$p_{n-2} - p_{n-1} = \frac{r_{n-2}^{-2} - r_{n-1}^{-2}}{r_{n-2}^{-2} + r_{n-1}^{-2}} (t_{n-2} + p_{n-1}),$$

or

$$p_{n-2} = \frac{r_{n-1}^{2} - r_{n-2}^{2}}{r_{n-1}^{2} + r_{n-2}^{2}} (t_{n-2} + p_{n-1}) + p_{n-1}. \quad (24)$$

giving p_{n-2} when p_{n-1} is known, and when t_{n-2} is assigned by its maximum allowable value in practice.

Also

$$t_{n-2} - t'_{n-1} = p_{n-2} - p_{n-1} \quad \ldots \quad (25)$$

thus determining t'_{n-1}; a knowledge of t'_{n-1} is required when we come to the determination of the amount of shrinkage necessary to produce p_{n-1}.

Proceeding successively in this manner, we finally obtain—

. . . .

$$p_2 = \frac{r_3^2 - r_2^2}{r_3^2 + r_2^2}(t_2 + p_3) + p_3 \quad . \quad . \quad . \quad . \quad \text{(iii.)}$$

$$p_1 = \frac{r_2^2 - r_1^2}{r_2^2 + r_1^2}(t_1 + p_2) + p_2 \quad . \quad . \quad . \quad . \quad \text{(ii.)}$$

$$p_0 = \frac{r_1^2 - r_0^2}{r_1^2 + r_0^2}(t_0 + p_1) + p_1 \quad . \quad . \quad . \quad . \quad \text{(i.)}$$

thus determining p_0, the maximum allowable powder pressure in the gun, for maximum working values of $t_0, t_1, t_2 \ldots t_{n-1}$; and these are the fundamental equations employed in gun-making.

(20) With no shrinkage, or a homogeneous gun, the maximum allowable powder pressure would be reduced to

$$t_0 \frac{r_n^2 - r_0^2}{r_n^2 + r_0^2},$$

so that we perceive the advantage of the shrinkage in strengthening the gun.

(21) In Fig. 5 the dimensions are taken from the American "Notes on the Construction of Ordnance," No. 31, by Lieut. Rogers Birnie, slightly altered to round numbers; the diameter of the powder-chamber of the 8-inch gun is supposed to be 10 inches; so that $r_0 = 5$; and we put $r_1 = 7$, $r_2 = 11$, $r_3 = 13$, $r_4 = 16$; instead of 4·75, 7, 11, 13·15, and 15·75, as given in the Note 31.

Now, solving equations (25), (iv.), (iii.), (ii.), (i.) with $p_4 = 0$, $t_3 = t_2 = t_1 = 18$, $t_0 = 15$, we shall find—

$$p_3 = \frac{16^2 - 13^2}{16^2 + 13^2} \times 18 = 3·7, \qquad t'_4 = 14·3;$$

$$p_2 = \frac{13^2 - 11^2}{13^2 + 11^2}(18 + 3·7) + 3·7 = 7·3, \; t'_3 = 14·4;$$

$$p_1 = 18, \qquad t'_2 = 7·3;$$

$$p_0 = 28·7, \qquad t'_1 = 4·3.$$

Thus, the maximum allowable powder pressure in the chamber of this gun is nearly 29 tons per square inch; so that if the pressure is limited to 17, the gun has a factor of safety $29 \div 17 = 1·7$.

Joining the tops of the ordinates for p_0 and p_1, t_0 and t'_1, &c., by Barlow's curves, we have the graphical representation of the maximum allowable firing stresses of this gun; in which it must be noticed that the area of the rectangle, $p_0 r_0 = 143·5$, is equal to the area of all the circumferential tension curves bounded by the jagged edge $t_0 t'_1 t_1 t'_2 \ldots$

(22) With a powder pressure $p_0 = 28·7$ (tons on the square inch) the powder stresses will be given by

$$t_0 = \frac{16^2 + 5^2}{16^2 - 5^2} \times 28·7 = 34·9,$$

$$p_1 = p_0 \frac{7^{-2} - 16^{-2}}{5^{-2} - 16^{-2}} = 13·1,$$

$$t_1 = t_0 - p_0 + p_1 = 19·3 = t'_1;$$

$$p_2 = 3·5, \quad t_2 = 9·7 = t'_2;$$

$$p_3 = 1·0, \quad t_3 = 7·2 = t'_3;$$

and

$$p_4 = 0, \quad t_4 = 6·2.$$

Subtracting these powder stresses from the firing stresses, we are left with the initial stresses in the gun in a state of repose, represented in Fig. 6, and given by

$$\begin{array}{lll} p_0 = 0, & t_0 = -19·9, & \\ p_1 = 4·9, & t'_1 = -15, & t_1 = -1·3; \\ p_2 = 3·8, & t'_2 = -2·4, & t_2 = -8·3; \\ p_3 = 2·7, & t'_3 = 7·2, & t_3 = 10·8. \\ p_4 = 0, & t'_4 = 8·1, & \end{array}$$

(23) The data to which the gun-maker works are, first, the calibre of the gun; and secondly, the maximum powder pressure to be expected at any point of the bore; from these data, and the quality of the steel at his command, and also from the capacity of his machinery in producing and shaping the various pieces, the gun-maker proceeds to calculate the requisite thickness and number of the coils, arranged so that the maximum working tension shall not exceed certain practical limits laid down (18 tons per square inch in the coils, and 15 in the tube).

Thus, suppose he is called upon to design the cross-section of a gun over the powder-chamber, 10 inches in diameter, to stand a pressure of 20 tons per square inch.

He will generally take a factor of safety, say 2, and allow for double the pressure, so that he puts $p_0 = 40$, and then $t_0 = 15$.

He has r_0 given as 5 inches, and now r_1 is settled by the manufacture of the solid steel block or log, which is bored out to form the inner tube A; and now he can calculate p_1 and t'_1.

Practical considerations of manufacture decide the thickness and external radius r_2 to be given to the jacket B; and now, knowing r_1, r_2, p_1, and $t_1 = 18$, he can calculate p_2 and t'_2.

Similar practical metallurgical and manufacturing considerations decide the most suitable thickness for the hoops C, D, . . . ; and when he finds the radial pressure has become zero (or negative) the gun-maker knows that he has given his gun sufficient thickness and strength.

(24) A rule, suggested by Colonel Gadolin, was originally found convenient, by which the radii of the coils were made to increase in geometrical progression; this rule, though useful when guns were formed of a steel tube strengthened with wrought-iron hoops, is obsolete now that steel is used throughout; it was, however, formerly employed as a first approximation in the tentative solution of the problem.

The Longitudinal Stress in the Gun.

(25) So far we have not yet taken into account the distribution of longitudinal tension in the gun; and it must be confessed that no satisfactory rigorous theory exists at present for the determination.

Practically it is usual to take the longitudinal tension as uniform across a cross-section, and as due to the powder-pressure in the bore, treated as a closed vessel, closed at one end by the breech-piece, and at the other by the projectile.

Thus, with r_0 and r_2 as the internal and external radii, and p_0 as the powder-pressure, the longitudinal tension will have its average value

$$\pi r_0^2 p_0 / \pi(r_2^2 - r_0^2) = p_0/(r_2^2/r_0^2 - 1) \quad . \quad . \quad . \quad (26)$$

tons per square inch.

The average circumferential tension being

$$p_0 r_0/(r_2 - r_0),$$

this longitudinal tension will be

$$\frac{r_0^2}{r_2^2 - r_0^2} \cdot \frac{r_2 - r_0}{r_0} = \frac{r_0}{r_2 + r_0}$$

of the average circumferential tension, reducing to one-half in a thin cylinder, in which we may put $r_2 = r_0$.

For this reason it was formerly considered safe to leave the longitudinal strength to take care of itself; but some alarming failures, in which the gun on firing drew out like a telescope, have shown the necessity of carefully hooking the coils together, to provide the requisite longitudinal strength.

The larger the gun, the greater the number of separate parts requisite in its construction, and the greater the difficulty of providing for longitudinal strength.

(26) By taking a simple cylindrical tube under given internal and external pressures, and supposing it closed by hemispherical ends, a certain theory of distribution of longitudinal tension can be constructed.

For while the cylindrical part has the same transverse stresses as previously investigated, the stresses in the hemispherical ends may be considered the same as would be produced if they were joined up into a complete spherical vessel, under the same applied pressures.

A similar procedure to that already given for the cylinder is shown by Rankine ("Applied Mechanics," § 275) to lead to radial pressure $p = ar^{-3} + b$, and tension $t = \frac{1}{2}ar^{-3} - b$, in all directions perpendicular to the radius r.

For equation (2) for the cylinder becomes modified in the sphere to

$$\int_{r_1}^{r} 2\pi r t dr = \pi r_1^2 p_1 - \pi r^2 p \; ; \quad . \quad . \quad . \quad . \quad . \quad (27)$$

or, differentiating with respect to r,

$$2rt = -d(r^2p)/dr$$
$$= -2rp - r^2dp/dr,$$

or

$$t = -p - \tfrac{1}{2}rdp/dr. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

(27) The first assumption of Barlow, that there is no cubical compression, gives $t = \frac{1}{2}p$; and therefore

$$dp/p + 3dr/r = 0,$$

or

$$pr^3 = a, \text{ a constant,}$$
$$p = 2t = ar^{-3}.$$

Rankine's second assumption of uniform hydrostatic stress gives $t = -p$; and therefore

$$dp/dr = 0, \; p = b, \text{ a constant.}$$

Hence, in the general case,

$$p = ar^{-3} + b, \; t = \tfrac{1}{2}ar^{-3} - b; \quad . \quad . \quad . \quad . \quad (29)$$

where a and b are determined from the given values p_i and p_o of the internal and external applied pressures; so that

$$p_i = ar_i^{-3} + b, \quad p_o = ar_o^{-3} + b,$$

$$a = \frac{p_i - p_o}{r_i^{-3} - r_o^{-3}}, \quad b = \frac{p_o r_o^3 - p_i r_i^3}{r_o^3 - r_i^3} \quad . \quad . \quad (30)$$

(28) We may now take $\frac{1}{2}ar^{-3} - b$ to represent the longitudinal tension at radius r in the cylindrical part of the closed vessel.

Unfortunately for the strict mathematical accuracy of this method, we must suppose the circumferential tension to change suddenly from its value given from the formula $ar^{-3} - b$ to one given by a formula of the form $\frac{1}{2}a'r^{-3} - b'$, in passing from the cylindrical part to the hemispherical end.

A. G. GREENHILL.

(*To be continued.*)

STUDIES IN BIOLOGY FOR NEW ZEALAND STUDENTS.[1]

IT is now generally recognized that of all recent works dealing with elementary natural science, none have more thoroughly revolutionized our methods of teaching than those of Huxley, well known; and the years 1875-77 will be for all time memorable to English-speaking students, as those which marked their publication. The principles therein laid down are now so well known and generally adopted, that explanation of them would be here superfluous. In his work on "Physiography" the author points out (preface, p. viii.) that any intelligent teacher will have no difficulty in making use of the resources of his surroundings, in the manner and to the end laid down by himself; and this, in the long run, is the refrain of the method by which he has effected the revolution alluded to. So far as external evidences go, this wise counsel appears to have been nowhere more readily acted upon than in New Zealand.

Prof. Hutton, now of Christchurch, New Zealand, early took the hint; and, in so doing, produced the first of the series of pamphlets now under consideration. He chose for his purpose the Shepherd's Purse (cf. NATURE, vol. xxiv. p. 188), and Prof. Parker, who succeeded him, has, in turn, prepared notes serial with those of his predecessor—upon "The Bean Plant" (1881), and now upon "The Skeleton of the New Zealand Crayfishes." During the interval between the publication of Prof. Parker's pamphlets there appeared the third of the series, entitled "The Anatomy of the Common Mussels (*Mytilus latus, edulis*, and *magellanicus*)." This, the work of Alex. Purdie, and the least didactic of the series, was originally presented as a thesis for the degree of M.A. in the University of New Zealand.

The pamphlets alluded to are illustrated—in the case of that before us, by six clear woodcuts; and those of Parker, with which we need now alone be concerned, chiefly depart from the precedent laid down by Huxley in their less rigid adherence to the single type organism chosen for study. Wherever parts of this are, by adaptive change, so modified as to be non-typical in structure, Parker has introduced supplementary descriptions of corresponding parts of less modified allies. The necessity for this mode of procedure is now generally recognized; and the only danger to be averted in the future is that of unconscious reversion to the old condition of the "*omnium gatherum* of scraps." Let the type organism be always adhered to as closely as possible. Prof. Parker has exercised, in the matter, a wise discretion; and, having availed himself of the researches of Boas, has given to the world of carcinologists a laboratory guide which cannot fail to be of great service to them. The arthropods of the genus *Palinurus* happen to have furnished him, a few years ago, with material for original observation; the results of his inquiry are brought to bear upon the needs of the beginner in the pamphlet before us, and the value of the latter is thereby enhanced.

In dealing with the morphology of the eye-stalk (and of the pre-oral region generally), Prof. Parker states the alternative views, and gives the names of their leading upholders. Although he adopts the belief that the ophthalmic and antennulary regions of the arthropod body do not form the first and second metameres, and introduces, in accordance therewith, a revised nomenclature, his remarks, when dealing with the real point at issue, are so framed as to leave the mind of the student unbiassed. And moreover, he has so arranged his book that consideration of this vexed question in morphology is deferred until the concluding paragraph. This is as it should be. He naïvely summarizes the position in the words:—

"The fact of the eye-stalk bearing a flagellum seems to prove conclusively that it and the antennule are homologous. The question then resolves itself into this: Are the eye-stalks and antennules appendages in the ordinary sense, *i.e.* lateral offshoots of the first two metameres, or are they to be looked upon as prostomial appendages comparable with the tentacles of Chætopods and the antennæ of insects?"

Mindful of comments upon the general question raised in the above, which have already appeared in this journal (NATURE, vol. xxxv. p. 506), we are of opinion that equally good arguments are still to be adduced on both sides. The extraordinary facts of development of the invertebrate nervous system which are now accumulating, render it doubtful if we are justified in regarding the prostomium as something so very different from the rest of the body as we are wont; and we are led to ask whether it may not merely represent a precociously differentiated portion of the common perisoma? If there is any truth in the belief that the symmetry of the bilateralia is a laterally compressed radial one, the probability that the prostomium may represent that which we suggest becomes vastly increased; and it is worthy of remark that that lobe in some Chætopods (*Nemodrilus, Phreoryctes*) so far conforms to the characters of a body segment as to become externally subdivided. Nor must it be forgotten that the *Catometopa* bear (especially the *Ocypodidæ*), an optic style which would appear to present us, in its variations, with a series of conditions transitional between that of the eye-stalk of Milne-Edwards's *Palinurus* (to which Parker appeals in seeking to show that that appendage and the antennules are homologous) and that of the ordinary podophthalmatous forms.

We congratulate the students of the University of Otago upon the good use which, in their interests, their Professor has made of the advice of his distinguished master. We cannot, however, allow to pass unnoticed the statement (p. 7) that the seventh abdominal somite (by which term Prof. Parker designates the telson) bears appendages only in Scyllarus. This is not the case, as has been previously pointed out in these pages (NATURE, vol. xxxii. p. 570). The supposed appendages, did they exist, would be at least peri-proctous in position; and, as there is reason to believe the antennules (which Parker, be it remembered, admits to be serially homologous with the ophthalmites) to have been originally peri-stomial, if not meta-stomial, the supposed peri-proctous appendages might, with equal reason, be denied homology with the other abdominal members.

Finally: the altered position of the sterna in the anterior cephalic region and the consequent displacement of their appendages is said to be "a result of the *cephalic flexure*, by which, in the embryo, the anterior cephalic sterna become bent strongly upwards." Allowance has not yet been made, in dealing with this question, for the fact that, in the Decapods, these changes are greatly exaggerated by the general enlargement of the cephalo-thoracic region, consequent upon the aggregation therein of the more important and specialized viscera, and upon specialization of the thoracic appendages for ambulation.

G. B. H.

[1] "Studies in Biology for New Zealand Students." No. 4. "The Skeleton of the New Zealand Crayfishes (*Palinurus* and *Paranephrops*)." By T. J. Parker, B.Sc., F.R.S., of the University of Otago. (Wellington: Colonial Museum and Geological Survey Department. London: Trübner and Co.)

THE MANCHESTER WHITWORTH INSTITUTE.

THE inaugural proceedings in connection with the formal organization and constitution of the Manchester Whitworth Institute took place on Thursday last, July 17. Among those present were Lord Hartington, Sir F. Leighton, Sir Joseph C. Lee, Sir J. J. Harwood, Mr. W. Mather, M.P., Sir Henry Roscoe, M.P., Mr. O. Heywood, and many representatives of educational institutions in the city.

The governors first held their inaugural gathering in the building which is to form part of the museum, and which stands in one corner of the park. Afterwards, a meeting was held in a tent in the park. At this meeting Lord Hartington said that, although he had not been aware that he would be called upon to address them before the evening proceedings, he was pleased to move a resolution which acknowledged the wise benevolence and generosity of the legatees of Sir Joseph Whitworth, and commended the Institute to the support of the public as subscribers and donors of works of art and books, and to the community of Manchester for a contribution from its municipal funds for maintenance. He described the new departure taken that day as of a very important and possibly momentous character—probably the most important and ambitious step which had been taken yet in the direction of the movement of technical and scientific instruction and art education. That undertaking was the embodiment of a great idea, and the charter of the institution appeared to have embodied the ancient idea of a University, under which various colleges independent of one another agreed to co-operate in a common management and government, while retaining a considerable independence for a common end and a common good. In one respect, however, the ancient course seemed to have been reversed, for the University was prepared to support the colleges, which were the technical and art schools, instead of the colleges supporting the University, as of old. In conclusion, he expressed a hope that the example of the Whitworth legatees would lead others, and especially the Corporation, to assist and promote the useful objects of the Institute.

The proceedings connected with the opening of the Institute were continued in the evening, when the Mayor entertained a distinguished company at a banquet in the Town Hall. The loyal toasts having been honoured,

The Mayor proposed the residuary legatees of the late Sir Joseph Whitworth.

Chancellor Christie, in responding, said it was the earnest desire of the late Sir Joseph Whitworth that his fortune should be employed in promoting the cause of education, and especially of science and art education. He desired that there should be a graduated system of schools and colleges, by which a deserving lad might rise from the lowest elementary school to the highest institutions for the teaching of science, literature, or art. How best to accomplish this exercised Sir Joseph Whitworth for many years, but he was never able to perfect a scheme. That work he left to his legatees, and they had already spent over £300,000 in carrying out what they believed to be his ideas, while other liabilities still remained.

Mr. Alderman Thompson proposed "Success to the Whitworth Institute."

The Marquis of Hartington, in responding, said that his connection with the question of technical education was an extremely slight and superficial one. He did not pretend to be be an expert on the matter, and he had only taken it up because he had been struck with the fact that every other country in Europe gave more time and money to the promotion of technical education in some form or another than did the English nation. This state of things was coincident with complaints of the great severity of the commercial and industrial competition to which we were exposed. He could not help asking himself whether there was any connection between our neglect of technical education and the increased severity of the competition to which we were exposed. Then there was another question. Suppose the severity of the commercial competition were due to other causes, were we giving ourselves every chance in neglecting the technical education of our industrial population? He thought it was scarcely possible to exaggerate the importance of this question. To us the maintenance of our place in the race of commercial and industrial competition was not a question of greater or less prosperity at any particular moment; it was not a question of being leader or follower in the world's civilization; it was for many millions of our population a question of actual existence. If, through any circumstances, we ceased to be the greatest producers of the necessaries the world required; if, through any circumstances, we ceased to be the greatest distributors of the wealth of the world, not only would these small islands cease to be the seat of a great empire, but their limited extent would fail to produce the materials of bare existence for millions of people whom our industrial supremacy alone had brought together and enabled to exist here. We had received from our predecessors a great inheritance—the commercial and industrial leadership of the world. Up to the present time that inheritance had not shrunk or dwindled. Our pre-eminence had been largely due to the natural advantages we had enjoyed, but we knew that the conditions of supremacy, such as we had hitherto enjoyed were not always permanent. History taught us that in ancient times Greece and her colonies, and in modern times Italy and Holland, enjoyed that commercial supremacy which had more lately been ours. That supremacy had passed away from those countries under the changing conditions of commercial and industrial enterprise in Europe, and it would be rash to predict that our natural advantages, to which we owed so much, were sure to continue. It would be impossible for human foresight to make adequate protection against what might happen, but it must be a great advantage to any nation when the leaders and captains of its industries and commercial pursuits were able to avail themselves of the most complete scientific education which it was possible to give. It was such considerations as these that had induced him upon more than one occasion to call the attention of his fellow-countrymen to the importance of this question. He could not pretend to do more. How these things were to be attained he left to experts to say. We might have long to wait before, by the action of the State, any measures would be taken which we might hope would place us on a footing as regarded technical and scientific education with other European nations, and it therefore gave him the greatest satisfaction to see that localities where the need was more especially felt had themselves taken the initiative, and had founded institutions for the purpose of making some advance in that which had been considered to be the business of the State in other countries. There was one feature of the present time which was calculated to give cause for just and legitimate satisfaction. He alluded to what he thought he saw in the growth of local public spirit. Such a spirit had never been altogether wanting among us. That it existed formerly among us was abundantly proved by the munificent foundations for religious, educational, and charitable purposes which our forefathers had handed down. There was a time when there was a tendency for even these ancient foundations to lapse into lethargy, and mismanagement began to prevail, but all that had begun to change, and now we had not only been occupied in reforming the abuses of those old foundations and institutions, so as to make them fully available for the new and growing wants of the people, but there had been shown to exist at the present time to as great an extent as formerly a disposition on the part of individuals who had acquired wealth in certain localities to use that wealth not for any selfish or personal purpose, but for the benefit and advantage of that population in the midst of which they had lived. He doubted not that the example which had been set by men like Sir Joseph Whitworth would be largely followed.

Sir Frederick Leighton also responded.

WEIGHTS, MEASURES, AND FORMULÆ USED IN PHOTOGRAPHY.

THE Photographic Convention of the United Kingdom, at a meeting held in the Town Hall, Chester, on June 26, considered the Report of a Committee which had been appointed to consider the weights, measures, and formulæ used in photography. The Committee consisted of W. Bedford, C. H. Bothamley (Secretary), A. Cowan, A. Haddon, A. Levy, A. Pringle, and G. Watmough Webster. The Report was drawn up by C. H. Bothamley. The following recommendations were unanimously adopted by the Convention:—

A. *Weights and Measures.*—(1) If the metric system be used, weights will naturally be expressed in grammes and measures in cubic centimetres.

(2) If the English units be used, the minim and the drachm should not be employed at all. All weights should be expressed either in grains or decimal parts of a grain, or in ounces and fractions of an ounce; all measures in fluid grains, or in fluid ounces and fractions of a fluid ounce.

B. *Formulæ.*—(3) Formulæ should give the number of *parts* of the constituents, by weight or measure, to be contained in some definite number of *parts, by measure*, of the solution. The mixture can then be made up with (*a*) grammes and cubic centimetres, or (*b*) grains and fluid grains, or (*c*) ounces and fluid ounces, according to the unit selected.

(4) The standard temperature for making up solutions should be 15° C. or 62° F. No appreciable error will be introduced by the fact that these two temperatures are not quite identical.

(5) Formulæ should give the quantities of the constituents to be contained in x parts of the finished solution, and not the quantities to be dissolved in x parts of the solvent. When a solid dissolves in a liquid, or when two liquids are mixed, the volume of the solution or mixture is, as a rule, not equal to the sum of the volumes of its constituents. The expansion or contraction varies with the nature of the solids and liquids and the proportions in which they are brought together. In making up a solution, therefore, the constituents should first be dissolved in a quantity of the solvent smaller than the required volume of the finished mixture, and after solution is complete, the liquid, cooled if necessary to the ordinary temperature, is made up to the specified volume by addition of a further quantity of the solvent.

(6) It is very important to specify, in the case of liquids, whether parts by weight or parts by measure are intended. The equivalence between weight and measure only holds good in the case of water and liquids of the same specific gravity: a fluid ounce of ammonia solution or of ether weighs less than an ounce; a fluid ounce of strong sulphuric acid weighs nearly two ounces.

(7) Whenever possible, formulæ should give the quantities of the constituents required to make up 10, 100, or 1000 parts of the solution.

(8) When a mixture (*e.g.* a developer) is to be prepared just before use from two or more separate solutions, it is desirable that the proportions in which the separate solutions have to be mixed should be as simple as possible—*e.g.* 1 to 1, 1 to 2, 1 to 3, 1 to 10.

(9) When metric units are employed, the original French spelling, "gramme," should be used in preference to the contracted spelling, "gram," in order to avoid misreading and misprinting as "grain."

SCIENTIFIC SERIALS.

IN the *Journal of Botany* for June and July we find contributions to systematic and descriptive botany by Mr. E. G. Baker, on new plants from the Andes, and on the genera and species of Malveæ; by Mr. F. N. Williams, a synopsis of the genus *Tunica* of Caryophyllaceæ, and others.—Mr. A. Fryer records what he believes to be an example of hybridity in *Potamogeton.*—Mr. H. T. Soppitt describes a new parasitic fungus, *Puccinia digraphidis*, the teleutospore-form of which occurs on *Phalaris arundinacea*, while the æcidio-form is parasitic on *Convallaria majalis.*

THE original papers in the *Nuovo Giornale Botanico Italiano* for July all refer to the geographical distribution of Italian plants, chiefly Hepaticæ and Fungi. Among the papers read at the meetings of the Italian Botanical Society the following are of special interest:—Signor O. Kruch contributes to our knowledge of the foliar fibrovascular bundles of *Isoetes.*—The exhaustive researches of Prof. Arcangeli on the structure of the various organs in the Nymphæaceæ are represented by an account of the leaves of *Nymphæa* and *Nuphar.*—Signor U. Martelli gives a very interesting account of the dissociation of a lichen (*Lecanora subfusca*) into its constituent algal and fungal elements, the complement of Stahl and Bonnier's observations on the synthesis of lichens.—Prof. Arcangeli describes the carnivorous habits of an Aroid, *Helicodiceros muscivorus.*

American Journal of Science, July, 1890.—The inconsistencies of utilitarianism as the exclusive theory of organic evolution, by Rev. John T. Gulick. The author criticizes various conclusions arrived at by Mr. Wallace in his volume on "Darwinism."—The southern extension of the Appomattox formation, by W. J. McGee. In a paper entitled "Three Formations of the Middle Atlantic Slope," published in this *Journal* in 1888, a distinctive late Tertiary formation well displayed on the Appomattox River in Eastern Virginia was defined and named after that river; and its principal characters, distribution, stratigraphical relations, and probable age were recorded. The present number contains the result of an extension of the research into the Carolinas, Georgia, Alabama, and Mississippi.—An experimental proof of Ohm's law, preceded by a short account of the discovery and subsequent verification of the law, by Alfred M. Mayer. The experiment described is very suitable for lecture demonstration, and all details are given. A low-resistance Thomson galvanometer is joined up to a box containing coils of 1, 2, and 3 ohms resistance, and to a coil of wire wound round a disk of wood which slides on an upright magnet 1·5 cm. in diameter. The quick movement of this coil causes the production of a magneto-electric current, and adopting the conception of the lines of magnetic force it may be said that a ring with one coil cuts a certain number of these lines, this cutting of the lines causes the current, and is the electromotive force. A ring with two, three, or four coils cuts two, three, or four times the number of lines, and increases the electromotive force in the same proportion. The resistance in the circuit can also be changed by means of the resistance coils, and hence it can be proved that the current is directly as the electromotive force and inversely as the resistance by observations of the galvanometer deflections.—Microscopic magnification, by W. Le Conte Stevens. If F be the equivalent focal length of the eye-piece of a microscope, f that of the objective, T the tube length, and D the distance of distinct vision, the magnification, M, is expressed by the formula $M = \frac{(D+F)(T-f)}{Ff}$.—Notes on the minerals occurring near Port Henry, N.Y., by J. F. Kemp.—Occurrence of goniolina in the Comanche series of the Texas Cretaceous, by Robert T. Hill.—A method for the reduction of arsenic acid in analysis, by F. A. Gooch and P. E. Browning.—On the development of the shell in the genus Tornoceras, Hyatt, by Dr. Charles E. Beecher.—Fayalite in the obsidian of Lipari, by Jos. P. Iddings and S. L. Penfield.—On some selenium and tellurium minerals from Honduras, by Edward S. Dana and Horace L. Wells. The locality from which the minerals were obtained is the El Plomo mine, Ojojoma District, Department of Tegucigalpa, Honduras. An analysis of one showed that it contained 29·31 per cent. of selenium and 70·69 per cent. of tellurium, the great proportion of selenium constituting it the nearest opproach to native selenium which has yet been found in nature. It is proposed to call this mineral selen-tellurium. Some tellurium-iron minerals are also described.—Some connellite from Cornwall, England, by S. L. Penfield.

American Journal of Mathematics, vol. xii., 4 (Baltimore, July 1890).—This number opens with a short note (pp. 323-336) on confocal bicircular quartics, by Prof. Franklin, and closes with a memoir on the theory of matrices, by H. Taber (pp. 337-396.) The memoir is a full investigation of the subject, touching upon the results already obtained by Cayley ("Theory of Matrices," *Phil. Mag.*, 1858), Hamilton ("Quaternions," 1852), the two Peirces, and Clifford. The writer was not aware of Buchheim's paper, with an identical title, in the London Mathematical Society's Proceedings (vol. xvi.) until after his own paper was written. There is much which is substantially the same in the two memoirs, but Mr. Taber claims to have "treated the whole subject more in detail and more systematically than Mr. Bucheim" (*sic*).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 15.—M. Hermite in the chair. New studies on the rotation of the sun, by M. H. Faye. An account is given of Dr. Wilsing's observations of faculæ for the purpose of determining the time of rotation, and of the recent work done by M. Dunér, in which Fizeau's method was adopted.—On the photography of the polarization fringes of crystals, by MM. Mascart and Bouasse. A method of obtaining photo-

graphs of these fringes is described.—On the freezing of meat by cold liquids, by M. Th. Schlœsing. A new method for freezing and preserving large quantities of meat is described.—The active elasticity of muscle, and the energy used in its creation, in the case of dynamic contraction, by M. A. Chauveau.—On linear differential equations, by M. Cels.—Method of measuring the difference of phase of the rectangular components of a refracted light-ray, by M. Bouasse.—On the measurement of the vapour-tension of solutions, by M. Georges Charpy. The author uses the condensation hygrometer to determine indirectly the tension of the vapour above the solution employed.—On the laws of Berthollet, by M. Albert Colson.—Researches on the double nitrites of rhodium, by M. E. Leidié. Double nitrites of rhodium and potassium, sodium, ammonium, and barium respectively are described, methods of preparation and properties of each salt being given.—On some combinations of camphor with phenols and their derivatives, by M. E. Léger. Many of the compounds obtained yield crystals of definite form and constant composition, and are hence proved to be true compounds.—On mannite hexachlorhydrin, by M. Louis Mourgues. The method of preparation and properties of this body are given; its analysis indicates that it possesses the formula $C_6H_8Cl_6$. Raoult's method gives its molecular weight as 278; the writer is of opinion that its constitution corresponds to $CH_2Cl(CHCl)_4CH_2Cl$.—On some new derivatives of β-pyrazol; a contribution to the study of the nitric ethers, by M. Maquenne.—Researches on the division of the embryonic cellules among the Vertebrata, by M. L. F. Henneguy.—On the colouring reagents of the fundamental substances of membrane, by M. L. Mangin. The author compares the action of colouring matters of membrane with their chemical composition, and establishes the results furnished by the colouring reagents by chemical analyses of the tissues.—On the expansion of silica, by M. H. Le Chatelier. The experiments show that amorphous silica expands very little between 600° C. and 1000° C. Quartz expands regularly up to nearly 600°, and then reaches a point where increase of temperature causes contraction. Calcined chalcedony expands slowly up to 200°, then the coefficient of expansion is enormously increased for a time, but finally it returns to the original value. Tridymite behaves much like chalcedony, expanding slowly up to about 120°, when an abrupt change takes place; the slow expansion then returns again, and finally contraction takes place with increase of temperature. Thus the change in the coefficient takes place at a higher temperature in the minerals of high density (quartz, chalcedony) than for those of lower density (tridymite and calcined chalcedony).—Analysis of the menilite of Villejuif, by M. Auguste Terreil.—On the prediction of storms by the simultaneous observation of the barometer and the higher atmospheric currents, by M. G. Guilbert.

AMSTERDAM.

Royal Academy of Sciences, June 28.—Prof. van de Sande Bakhuyzen in the chair.—Dr. Beÿerinck described experiments relating to the culture of Zoöchlorella, Lichen gonidia, and other lower Algæ in a pure state.—The same speaker treated of the artificial infection of *Vicia Faba* with *Bacillus radicicola*. Twelve pots filled with sterilized river-sand, which was rendered very poor in nitrogen by washing with distilled water, were divided into four sets, each of three. On April 25, a well-sterilized seed of *Vicia Faba* was planted in each pot. The pots were of such a construction that the dust of the air was wholly excluded from the sand, and the watering could also take place under perfect dust-exclusion. The first set was watered with a mixture of 0·1 monopotassium phosphate, 0·03 calcium chlorate, 0·06 magnesium sulphate, pro 1 litre distilled water; the second set with the same mixture; the third set with the same mixture, to which was added 0·2 gr. calcium nitrate; the fourth set with the same mixture, to which was added 0·2 gr. ammonium sulphate. When the plants had developed their second leaf, the three pots of the first set, and one single pot of each of the three latter sets, were infected with a gelatine culture of *Bacillus radicicola* var. *fabæ*, cultivated in 1889 from the tubercles of *Vicia Faba*, and since that time kept in successive cultures. The bacteria wherewith the infection took place were mixed with sterilized common water. On June 20 there was found on one old cotyledon a *Penicillium*, and therefore the experiment was not further continued. All the plants were taken from the pots, and their roots well washed and examined; every single one of the six infected plants bore many tubercles, whilst no single one of the six remaining not infected plants showed the least sign of tubercles. The presence or absence of nitrogen as nitrate or as ammonium is therefore indifferent with regard to the practicability of the infection. By another set of experiments it was shown that gelatine cultures of *Bacillus ornithopi*, cultivated in 1889 from the tubercles of *Ornithopus perpusillus*, had no power to infect *Vicia Faba*. But negative results are not equal to positive in value.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Evolution of Photography: J. Werge (Piper and Carter).—Higher Geometry, W. J. Macdonald (J. Thin).—Zoological Types and Classification: W. E. Fothergill (J. Thin).—Principles of General Organic Chemistry: Prof. E. Hjelt, translated by J. Bishop Tingle (Longmans).—Philosophy of Tumour Disease: C. Pitfield Mitchell (Williams and Norgate).—Diseases of Crops and their Remedies: A. B. Griffiths (G. Bell and Sons).—Principles of Economics, vol. i.: A. Marshall (Macmillan and Co.)—Elementary Text-Book of Heat and Light: R. Wallace Stewart (W. B. Clive and Co.).—Quarterly Review, July (Murray).—The Forum, July (New York).—Electrical Engineer's Pocket-Book: H. R. Kempe (Lockwood).—Monograph of the British Cicadæ, Part III.: G. B. Buckton (Macmillan and Co.).

LAVOISIER.

La Révolution Chimique : Lavoisier. Par M. Berthelot. (Paris : Félix Alcan, 1890.)

AMONGST the crop of literature which the centenary of the French Revolution has produced, there are probably no works more interesting to the historian of science in general, and certainly none more interesting to the historian of chemistry in particular, than the two biographies of Lavoisier which then appeared, the one due to the patient industry of M. Grimaux, and the other to the patriotic zeal of M. Berthelot. These works have necessarily much in common, but they differ essentially in the standpoint from which their authors regard thei subject. M. Grimaux's book was the first to make its appearance. It deals more especially with the public life of Lavoisier, with his work as a *fermier-général* and at the *Régie des Poudres*, and with his labours as an economist and as a social and political reformer. To a reader but little versed in the history of science the general tendency of M. Grimaux's work is to place in high relief the political side of Lavoisier's career ; and to magnify the servant of the State at the expense of the chemist. Hence it was but proper and natural that M Berthelot, the Perpetual Secretary of the Academy, should have felt urged to set forth in a clearer light the nature of the service which his illustrious predecessor, who fought so nobly for the Academy during the dark days of the Great Terror, has rendered to science. M. Berthelot has accordingly occupied himself almost exclusively with the scientific part of Lavoisier's work. If he dwells at all on the details of his career as an administrator, it is only for the purpose of explaining the conditions which directed, controlled, or in any way modified the course of his investigations. For the greater part of these details he is mainly indebted to M. Grimaux. M. Berthelot has, however, enjoyed this advantage over M. Grimaux, that he has been in a position to study the minutes of the Academy, more especially at about the period of the Revolution, and he has had the rare privilege of being able to peruse the laboratory journals of Lavoisier, which had been preserved by the pious care of Madame Lavoisier and her descendants. These documents are of the greatest interest and importance, for they enable us not only to determine the exact time and sequence of his researches, but also to trace the gradual development of his conceptions, and the manner in which he shook himself free from the trammels of phlogistonism. These registers, thirteen in number, are deposited in the Archives of the Institute. They have been most carefully examined and collated by M. Berthelot, and a statement of the results of the analysis forms a considerable and specially valuable section of his work.

It is a remarkable circumstance, as M. Grimaux has already stated, that, in spite of the glory which surrounds the name of Lavoisier, a century should have elapsed before any substantial effort should have been made to do justice to his memory. Beyond the *éloge* by Fourcroy (inspired, there is too much reason to fear, by the extraordinary revulsion of public feeling which immediately followed the death of Robespierre), and the short biographical notices by Lalande and Cuvier, there had been no real attempt to deal with the career of the man whom his countrymen regard as the Newton of chemistry until the appearance of M. Grimaux's book. Dumas—who exercised such a predominant influence on chemical thought in France, and who throughout his life professed the most fervent admiration for Lavoisier, the official republication of whose works he superintended—never did more towards the realization of his oft-repeated intention of producing such a monograph as M. Grimaux has now given us than is to be seen in a few enthusiastic pages, more eloquent, perhaps, than exact, in his "Leçons de Philosophie Chimique." The tardiness of this reparation does not fail to strike M. Berthelot, and he ventures to discuss its cause. We do not propose to follow him in this. *Qui s'excuse s'accuse :* the conclusion is not creditable to the national fame or to its sense of retributive justice. No statue of Lavoisier is to be found in the city of his birth and death. Republican Paris is apparently unwilling to give any outward and visible sign of contrition for the great crime of May 8, 1794.

It is hardly surprising that in a book written at a time when France had invited the world to assist her to commemorate an epoch which had such a tremendous influence on her destiny, M. Berthelot should have sought and found a parallel between the work of Lavoisier and the great upheaval which so completely changed the social and political aspect of his country. The active revolt against phlogistonism no doubt had its origin in France, and Lavoisier was unquestionably the leader in the revolution. That, however, is not saying that he was the actual author of it. Black, who in this as in other matters was far ahead of the scientific thought of his age, had already convinced himself of the inadequacy of Stahl's generalization even as a theory of combustion, and Black's influence still counted for something in this country. Indeed, as Lavoisier admits, it also counted for much with at least one man in France, and that man was Lavoisier himself. He spoke of Black as "le savant illustre qui le premier a réuni et mis en corps de doctrine le phénomène de la fixation de l'air dans les corps." Black's great discovery was, in fact, the real beginning of *la révolution chimique.* M. Berthelot is constrained to admit this.

"La théorie du phlogistique recevait par là une première atteinte : les changements survenus dans les propriétés de la chaux et des alcalis caustiques se trouvant expliqués, non par la présence ou l'absence de cet agent mystérieux, comme on l'avait fait jusque-là ; mais par celle d'une matière chimique déterminée, que l'on pouvait recueillir, peser, et transporter d'une combinaison dans une autre. Aussi les partisans de la théorie régnante se hâtèrent-ils de réfuter Black. Il s'engagea à cette occasion une première lutte, qui préluda à la grande discussion de Lavoisier."

Black, however, was not fitted to lead a revolution. A man of philosophic calm, gentle and somewhat retiring in disposition, he had nothing of the fire and energy of Lavoisier ; he hated controversy, and was constitutionally so indolent that it was only under pressure that he could be induced to write out the results of his investigations for publication. Black, who wrote French with ease—he was born at Bordeaux, and spent much of his

youth there—frequently corresponded with Lavoisier, and next to his friend Hutton there was probably no one who knew more of his opinions on current scientific topics. We have it on the authority of Thomas Thomson that Black felt hurt at the publication of several of Lavoisier's papers in the *Mémoires de l'Académie*, without any allusion whatever to what he himself had previously done on the same subject. Thomson adds, however, that, "from the posthumous works of Lavoisier, there is some reason for believing that, if he had lived, he would have done justice to all parties; but there is no doubt that Dr. Black, in the meantime, thought himself aggrieved, and that he formed the intention of doing himself justice by publishing an account of his own discoveries; however, this intention was thwarted and prevented by bad health" ("History of Chemistry," vol. i. 330).

We have ventured to say this much in justice to Black, not because we wish in any way to disparage Lavoisier, or to minimize the greatness of his services to the philosophy of chemistry, but because we think that M. Berthelot has allowed his analogy to run away with him. To say that Lavoisier was the actual author of *la révolution chimique* is hardly more true than the statement that Marat was the author of the Revolution of 1789. The learned author of the "Introduction à la Chimie des Anciens et du Moyen Age" stops short of attempting to prove the truth of Wurtz's saying that "chemistry is a French science; its founder was Lavoisier of immortal memory;" but we cannot help thinking that the circumstances under which his book was produced have in some measure warped his critical faculty; and that, seduced by analogy—that fruitful parent of error—he has been led to claim for his hero a pre-eminence in the creation of the new order of things that the unbiassed historian could not possibly grant.

T. E. THORPE.

THE ORGANISMS INFESTING WATER-WORKS.

Die Pflanzen und Thiere in den dunkeln Räumen der Rotterdamer Wasserleitung. Bericht über die Biologischen Untersuchungen der Crenothrix-Commission zu Rotterdam, vom Jahre 1887. Erstattet von Hugo de Vries. (Jena: Gustav Fischer, 1890.)

THE water-works of Rotterdam obtain their supply of water from the River Meuse, and apparently were able to filter and purify it in a satisfactory manner until the spring of 1887, when the Schizomycete *Crenothrix Kühniana* made its appearance in great abundance in the various reservoirs and aqueducts. This gave rise to so much trouble and difficulty in obtaining a pure water-supply, that new and improved filters were made, and finally a Commission of investigation was appointed, which carried on its work chiefly during the winter 1887–88. Some further questions bearing on the matter were investigated in the following year, and now we have before us the chief scientific results of the Report sent in by the Professor of Botany at Amsterdam, Hugo de Vries, and giving a most interesting account not only of this particular pest, the *Crenothrix*, but also of the other plants and animals found living in the dark places of the Rotterdam aqueducts.

A small laboratory was fitted up in the water-tower of one of the reservoirs, so that Prof. de Vries and Dr. F. Dupont, who conducted the microscopical investigations, might have every opportunity of examining the plants and animals in a living condition. In the first part (50 pages) of the paper the attached organisms found in the aqueducts in 1887 are described, beginning with *Crenothrix Kühniana* (one of the "iron-bacteria"), of which a full account, with figures, is given. This organism was found to be undoubtedly the chief cause of the impurity of the Rotterdam water-supply, as it also had been in the case of the "water-calamity" of Berlin in 1878. Its powers of reproduction are so enormous that in a very short space of time it can spread in abundance over a wide area and render a vast amount of water impure. De Vries comes to the conclusion from his observations that *Crenothrix* does not vegetate in the soil, as had been supposed to be the case by Brefeld and Zopf in the Berlin investigations, but is derived merely from the basins and canals of unfiltered water.

The fixed plants and animals—(1) in the Meuse and in the open basins, (2) in the covered-in canals for the unfiltered water, and (3) in the dark chambers containing the purified water—are successively described, and various interesting observations noted. *Spongilla* (*Meyenia*) *fluviatilis* was found, in the dark passages, covering the walls in a thin layer, and was of a white colour, in place of being green as it is when exposed to the light. The fresh-water mussel, *Dreyssena polymorpha*, and the hydroid zoophyte *Cordylophora lacustris* were found in great abundance in some parts; lower worms, Rotifers, Infusoria, some Crustacea, and a few Molluscs in others; and a luxuriance of fresh-water Polyzoa of the genera *Plumatella* and *Paludicella* in other parts of the system—over 30 species in all being observed, and these very much the same forms which Kraepelin had found in the Hamburg aqueducts, and Potts in those of Philadelphia—while *Crenothrix* was present everywhere, apparently covering everything in great abundance. In the filters, however, and in the channels containing filtered water, only *Crenothrix* and a few other Algæ were found. The Sponges, Zoophytes, Polyzoa, and Molluscs were entirely absent.

The second part of the work deals with the free-swimming animals—the fresh-water Crustacea. Of these, two species, *Asellus aquaticus* and *Gammarus pulex* unlike the attached animals (Polyzoa, &c.), are able to penetrate into the filtered waters along with the *Crenothrix*; and in 1887 these Crustaceans developed in the purified water to such an extent as to be a perfect plague, thus giving an excellent example of the rate of increase of a species unchecked (for a time, at least) by competition. The *Gammari* and *Aselli* which penetrated to the filtered waters had the field to themselves, they had found a niche of nature previously unoccupied by any animals, they had food and other conditions necessary for life, and plenty of room, so they increased with astonishing rapidity.

In regard to their nourishment, the *Gammari* were found by de Vries to subsist upon the *Crenothrix*, which they thus to some small extent helped to keep down; while the *Asellus*, as was proved by an

examination of the fæcal pellets and of the alimentary canal, eats the wood-work used in the construction of the filters, and also the hyphæ, conidia, &c., of the Fungus *Melanomma pulvis-pyrius*. The *Aselli* are found to eat away the softer spring wood of the beams, and leave the harder autumn wood of the annual rings standing out as ridges. Consequently one important practical conclusion at which the Rotterdam Commission arrived was that the wooden beams in the filters should be removed, and their place be taken by cement, which would not afford shelter and nourishment to the Crustacea, Fungi, and other organisms. The Report is illustrated by woodcuts, and a plate giving a plan of the Rotterdam water-works, so as to show the connection between the various reservoirs and aqueducts and the course taken by the water in passing through the system.

W. A. HERDMAN.

AMERICAN GEMS.

Gems and Precious Stones of North America: a Popular Description of their Occurrence, Value, History, Archæology, and of the Collections in which they exist; also a Chapter on Pearls, and on Remarkable Foreign Gems owned in the United States. Illustrated with Eight Coloured Plates and numerous minor Engravings. By George Frederick Kunz. (New York: The Scientific Publishing Company, 1890.)

THE general dissociation in Nature of useful and ornamental materials, which has often been commented upon, finds nowhere a more striking illustration than in the North American continent. Rich as this part of the globe is in coal, the ores of iron, and of almost all the metals employed in the arts, as well as in all kinds of building materials, yet the value of gem-stones found within its limits is practically insignificant. As the author of the work before us admits,

"the daily yield from the iron and coal mines, or from the South African diamond mines, or a week's yield of the granite quarries, would exceed in value the entire output of precious stones found in the United States during a year."

Small though their aggregate value may be, however, there are many facts concerning the variations in character and the mode of occurrence of these interesting and beautiful objects, the gem-stones, which can better be studied in North America than in any other part of the world. Nor could we possibly wish for a more fully informed guide than Mr. Kunz: his skill as a mineralogist is well known, and he has frequently, in his capacity of gem-expert to Messrs. Tiffany and Co., been able not only to reject the spurious but to recognize for the first time the latent capabilities of mineral varieties not previously employed as gems. Since the year 1883, Major J. W. Powell, the Director of the U.S. Geological Survey, has published a valuable series of annual volumes on "The Mineral Resources of the United States"; and the chapters on precious stones in these reports have been written by Mr. Kunz.

The book aims at combining the exact information required by the mineralogist with the curious and sometimes trivial, but by no means unimportant, lore dear to the collector and the archæologist. As is fitting in such a work, the typography and illustrations are of remarkable excellence, and reflect the highest credit upon the printers and engravers of the United States; indeed, it would be hard to find anywhere a volume which combines so many excellences, alike in the paper, printing, plates, and binding.

Every care has evidently been given to making the scientific part of the work trustworthy; and we may especially refer to the chapters which deal with the corundums, the beryls, and the felspars of the United States, as containing much new and valuable information. The details concerning the silicified ("jasperized") woods of Arizona given in this book are more complete and satisfactory than any that have before appeared, while the accounts of the pearls and pearl-fisheries of North America are full of interest. In order to make the work more complete, the twelve chapters on the gems of the United States are followed by two others on the precious stones of Canada and Mexico respectively. Little more than an enumeration of the gem-stones of the Dominion can be given in the space at the command of the author, but more justice is done to the jades, opals, and obsidians of Mexico.

The two last chapters deal respectively with the lapidaries' work performed by the aborigines of North America, and the work of the same kind now being done in the country; and both chapters abound with curious and interesting facts. The publication of this book cannot fail to call attention to the importance of systematic searches being carried on with a view to the discovery of some of the more valuable gem-stones, in districts where no authentic account of their occurrence at present exists. Collectors, archæologists, jewellers, and dealers will all find their respective wants anticipated by Mr. Kunz; and by attention to the methods of discrimination and the detection of fraud which he indicates, will be saved frequent disappointment and much pecuniary loss.

J. W. J.

OUR BOOK SHELF.

Timbers, and how to Know Them. By Dr. R. Hartig, Professor of Botany in Munich University. Translated by W. Somerville. (Edinburgh: Douglas, 1890.)

THE original of this little book is the third edition of a small pamphlet entitled "Die Anatomischen Unterscheidungsmerkmale der wichtigeren in Deutschland wachsender Hölzer," and why the translator should have altered the significance of the title is not explained. In any case it would not be easy to justify the more ambitious title of the English translation, seeing that no additions have been made to the original, and that the original title claims too much. For the book does little more than give in bare outline the more conspicuous features observed on the transverse sections of our common woods; and although this is done fairly well, the treatment is neither exhaustive nor free from defects.

The only other alterations made by the translator are the additions of an index and a glossary. The former appears adequate and useful, the latter has shortcomings, especially under the headings "bordered pit," "parenchymatous cells," &c. Definitions such as "*Vertical resin-duct*, one which runs longitudinally, *i.e.* parallel to the outside of a stem," are, to say the least, not improved by the additional remark.

With regard to the actual translation, it is good and

accurate on the whole: so faithful is it that Mr. Somerville has omitted to correct Hartig's own mistake as to the generic name of the teak, which reappears in the English edition as *Tectonia*—surely the translator knows it should be *Tectona!*

The chief defects in the original pamphlet may be summed up in that characters are relied on for distinguishing closely allied woods which do not serve the purpose. For instance, the broad medullary rays, so called, of the alder are a very treacherous guide; and the admission that the wood of *Æsculus* "occupies a position midway between" the hard and soft woods, itself shows how useless the property of hardness is, as a class character, unless defined in a rigid manner.

Both the selection and the description of the seven exotic timbers mentioned in the appendix are faulty, and we are driven to the conclusion that there is room for a much better book on the subject than the little pioneer under review. As a pioneer, however, it is to be welcomed, with its useful, compact information, as well as its failings.

Advanced Physiography (*Physiographic Astronomy*). By John Mills. (London: Chapman and Hall, 1890.)

THE introductory part of this book is a reprint of the elementary lessons in the subject by the same author (NATURE, vol. xlii. p. 76), and the remainder is intended to meet the requirements of advanced students in connection with the Science and Art examinations. The new material constitutes a fair general outline of the subject, but some of the descriptions suffer from want of detail. There are also indications of the author's unfamiliarity with some parts of the subject. On p. 248, for example, it is evident that the author is not well acquainted with stellar nomenclature, as he does not seem to be aware that Roman capitals are reserved for recently discovered variable stars. Again, on p. 253, he gives some figures relating to variable stars, which he evidently does not understand; he forgets to point out that Dunér's observations of stars were all of one spectroscopic group, and that the numbers given show that the maximum of variability occurs in that particular group. It should be an author's duty to use no term which he has not explained, but on page 114 he refers to the moon's mean horizontal parallax, although the meaning is not even hinted at.

The excellent plan of writing a head-line over each important paragraph has been adopted, but has not been employed consistently throughout. Thus, under the heading "To weigh a planet having a satellite," we find also a reference to the determination of the masses of the moon and the satellites of Jupiter and Saturn; and again, the chapter headed "Celestial Photography" consists largely of terrestrial magnetism.

The illustrations are numerous, but of varying quality; it is difficult to imagine what kind of telescope would give such a view of the moon as that represented in Fig. 93.

Travels in Africa. By Dr. Wilhelm Junker. Translated from the German by A. H. Keane, F.R.G.S. (London: Chapman and Hall, 1890.)

THE work of which this is a translation records Dr. Junker's experiences as a geographical explorer from the year 1875 to 1878. Besides an excursion to the Siwa Oasis and Natron Valley, it includes "a careful survey of the Báraka watercourse, wanderings through Upper Nubia, an expedition to the Sobat River, and numerous journeys throughout Makaraka Land and surrounding regions." It is to his later work that Dr. Junker chiefly owes his fame as an explorer; but in the present volume he gives an account of many notable achievements, and, as the translator points out, his descriptions of Makaraka Land and neighbouring districts will supply cartographers with plentiful material for filling up their blank spaces in an extensive region. Dr. Junker is a good writer as well as a bold and scientific traveller, and no one who begins to read his narrative will find it hard to go on to the end. The translator has done his work carefully, and the interest of the story is much increased by a valuable map and many good illustrations.

Selected Subjects in connection with the Surgery of Infancy and Childhood. By Edmund Owen, M.B., F.R.C.S. (London: Baillière, Tindall, and Cox, 1890.)

IN this volume Dr. Owen has published (by request) the Lettsomian Lectures delivered by him at the Medical Society of London in the present year. The position of Lettsomian Lecturer has been held by so many illustrious members of the profession that he seems to have undertaken with diffidence the task entrusted to him. The subjects with which he decided to deal have of late, as he says, been attracting considerable attention; and no one can doubt that they are of great practical importance. Dr. Owen discourses on them not only with learning, but with the directness, clearness, and force that spring from careful and long-continued observation.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Correspondence on Russian Transliteration.

AS absence from England prevented our replying at the time to the last letters on the system of Russian transliteration proposed in NATURE (vol. xli. p. 397), we thought it best to delay reply till any further communications from foreign correspondents had arrived. Since our last note (NATURE, vol. xli. p. 535) four letters have been received:—

(1) Mr. Wilkins (NATURE, May 22, p. 77) writes from Tashkend to point out that the system fails to distinguish between the few Russian words which differ only in their final semi-vowel. This is quite correct, but could only be avoided by the adoption of a separate symbol for each of these two characters and their retention at the ends of words. The addition to the trouble of printing that this would involve would be far more serious than the chance of error: *krob*, a roof, is hardly more likely to be confused with *krob*, blood, than, in a quite analogous case, is the German *band*, a volume, with *band*, a ribbon.

We do not accept Mr. Wilkins's criticism that *ui* does not "even remotely" represent the sound of ы. In the use of the letter in such a word as Полный we fully admit that this is so; but in other cases, as after a labial, it seems to us to represent the sound fairly well. Phonetically, Prībuilov (to take Mr. Wilkins's own case) is not so exact as Prībūəlɔff, as the word would probably be rendered by the elaborate refinements of the "Historical English Dictionary"; but even this is inadequate. We despair of any correct phonetic rendering of Russian words in English characters till a system is arranged on the lines of Dr. Murray's; and then the word would appear in some such guise as Ꝑɪɪbūəlɔfɪf. *Ui* seems to us on the average, and certainly in the case chosen by Mr. Wilkins, a better phonetic equivalent than *y*—a letter which is unfairly overworked in nearly all systems of transliterations, and which we have reserved exclusively for the double symbols *ya*, *ye*, *yu*.

(2) Mr. Wilkins, and our second critic, Baron Osten-Sacken (NATURE, May 22, p. 77), agree in condemning the adoption of *zh* for ж. A strong case can no doubt be made out for the claim of *j* to represent that letter, and *zh* was accepted (largely on phonetic grounds) as one of those mutual concessions which Baron Osten-Sacken commends. *Zh* has been largely used—almost universally in America—and it represents the sound better than the English *j*. No doubt the French *j* of *jour* is as near to it as the *zh* sound in the word *az(h)ure*. As the system proposed was intended for English-speaking countries we thought it inadvisable to adopt a French sound for one letter. The system is not so ambitious as Baron Osten-Sacken suggests it

should be. The methods of transliteration used in Germany and France differ so much from one another, and both from the English, that it seemed hardly possible, however desirable, to get one system adopted for the three languages.

In regard to Baron Osten-Sacken's other points, we regard *tch* and *stch* as inadvisable for ч and щ respectively, as, without the use of brackets, they would be mistaken for other sequences; and it was generally agreed that brackets should only be used as a very last resource. Finally, *æ* for the rare and practically extinct Ѵ is as good a phonetic equivalent as anything else, and more convenient than the already overburdened *y*.

(3) We cordially agree with the main point in Mr. Chisholm's argument (NATURE, May 1, p. 6), viz. that different systems are required for different purposes. The phonetic method adopted by the Geographical Society is unquestionably the best suited for their maps, but is quite inadequate for bibliographic use. We are glad to see that the system proposed for the latter purpose has Mr. Chisholm's approval.

(4) Mr. Groves (NATURE, May 1, p. 6) quotes a case that strikes him as very cumbrous; but we fail to see that the alteration to SKRJIPSKY is a sufficient improvement to be worth the inconveniences that the changes would involve in other cases. Under no system could a page of transliterated Russian hope to read like Addisonian English.

We do not see that, in the cases we quoted in our reply to Mr. Groves's former letter, we really misunderstood him. We do not know whence or how the three Gazetteers derived their renderings of Nizhniĭ; we only quoted them to show how many different spellings were current, and that the word, as transliterated by the new system, is neither unintelligible nor materially different from forms already in use. In the cases to which we attached most weight, viz. the titles of journals quoted from Scudder, Bolton, and the *Geological Record* the transliterations were certainly derived direct from the Russian, and we thought it probable that the Chemical Society's Journal would also have quoted the papers from the original rather than from second-hand German sources.

In conclusion, it is advisable again to repeat that the system was proposed solely for bibliographic use in the English language: the bibliographers who laid down the requirements of the system insisted that it should be based on two principles and should satisfy four rules. Had these been published in the original note, some subsequent criticisms would probably not have been made. Considering that the criticisms that really apply to this non-phonetic, unæsthetic system do not require any changes to be made in it, we hope that it will be adopted by other journals and catalogues. A supplementary list of those that do so will be published in the fuller account and explanation of the system that will be issued shortly.

H. A. MIERS.
J. W. GREGORY.

Discovery of a New Comet.

WHILE sweeping the northern sky at 11h. 35m. on the night of July 23, with a 10-inch reflector, power 40, I found a nebulous object near θ and ζ Ursæ Minoris, which I could not identify. It was faint, round, about 1′ in diameter, and with a very slight central condensation. I noted its position relatively to the stars near, but clouds then came over and prevented further observations for nearly an hour. On reobserving the object I found it to be a comet, a considerable displacement having occurred in its position.

On July 24 I obtained another view of it, and found its diurnal motion to be about 55′ to the south. At 11h. the comet was close to a star of about the ninth magnitude. At 11h. 40m. the comet was centrally projected upon the star, and the latter appeared to be involved in an extensive atmosphere. At about 12h. 30m. the comet reappeared on the other side of the star. I could not resist the impression that the star was decidedly fainter when the comet was passing over it.

The rough estimated positions of the comet were:—

	h.		°	°
July 23,	12 ...	...	228	+ 78
,, 24,	12 ...	...	228	+ 77

On July 25 and 26 the sky was cloudy and the comet not seen. It will be invisible during moonlight, but on about August 5 or 6 it ought to be picked up before moonrise in the region between γ Ursæ Minoris and ι Draconis, or at about 226° + 66°.

It is probable that this comet is approaching its perihelion and becoming brighter, in which case it may be readily seen when the sky is clear and free from moonlight.

Bristol, July 27. W. F. DENNING.

P.S.—The comet was observed at Nice on July 25, 10h., when its R.A. was 15h. 14m. (228½°), Decl. 76° 37′ N.

The Rotation of Mercury.

IN the February number of *Himmel und Erde*, and elsewhere, I have seen "that the otherwise meritorious, but in his observations and their discussion not always cautious and strict Schroeter," took the rotation period of Mercury to be twenty-four hours, but that Schiaparelli has now found that Mercury behaves to the sun as the moon to the earth, always showing the same side. The reporter also explained, by way of compliment to Prof. G. Darwin, why the planet next to the sun should differ in this respect from its companions.

As all astronomers like fair play, I went through Schroeter's papers, and read Schiaparelli's letter, No. 2944, *Astronomische Nachrichten*, which shows the usual industry, lucidity of style, and good faith of the Professor.

Schroeter and his companion Harding found the southern hemisphere of the planet rounded (*rundlich*) like the northern, but believed that they saw every twenty-four hours a certain change of form of the southern end of the lighted crescent, not perceptible in the northern. This was the leading observation, of which Schiaparelli remarks: "Of all facts known with regard to Mercury's rotation, this reappearance about every twenty-four hours of a truncation of the southern horn is the most manifest and anciently known" ("un apparente troncatura del corno australe è il più manifesto e anticamente cognosciuto").

Schroeter and Harding had for some time tried in vain to trace on the face of the planet some spot confirming their conclusion, when one day Harding first and Schroeter afterwards perceived a dark streak appearing in the east and moving west over the face of the planet. Both observed the phenomenon, with varying distinctness and under different combinations, during many days, and held that it confirmed their original hypothesis. Schroeter found that considerable increase of the magnifying power of his instrument lessened the distinctness of the shading.

Schiaparelli commenced his investigation because he considered Schroeter's result doubtful, and had instruments far superior to those used ninety years ago.

He has observed Mercury since 1881 more than 500 times, and has made on the most favourable days about 150 drawings, "to say the truth of very unequal value, but nevertheless so far agreeing as to furnish a result." That is, drawings on which the admittedly indistinct and varying feeble shadings united into one dissolving view did not always appear to be the same. The author also tells us that he made "one of his best observations when the planet was only at 3° 2′ from the limb of the sun," and "the disk of the planet then appeared perfectly round and uniformly bright;" and finally confesses, "Of these forms and streaks I have endeavoured to give an idea on the annexed drawing without concealing from myself the futility of such an attempt."

The Professor first made use of his "eight-inch instrument," then of "the eighteen," which showed the shading less distinctly, so as to make him write, "I have the impression that if one looked with a still stronger instrument all would appear dissolved in still more minute formations."

He lastly formulates three hypotheses: (1) the period is 24 hours; (2) the period divides the 24 hours without remainders; (3) there is no rotation properly speaking. He adopts No. 3, and concludes that the different appearances are caused by the great libration consequent upon the large eccentricity of its orbit.

Should there be no farther hypotheses possible, when the results of research are so conflicting, indistinct, and variable?

R.

Birds and Flowers.

IN reference to Mr. Wallace's letter (p. 295) with regard to a note in NATURE (July 17, p. 279), I correctly quoted Mr. Scott-Elliot's remark, who says:—

"I am led to entirely disagree with Mr. Wallace's opinion that the colour of flower-seeking birds is quite unconnected with their habits. As a matter of fact a peculiar shade of red found

on the breast of *Cinnyris chalybea*, *C. afra*, *C. famosa*, *C. sonimanga*, and *C. bicollaris* is exactly the same as that which I found in the majority of ornithophilous flowers in South Africa. It is, moreover, not a common colour in flowers; and since Labiatæ, Aloes, Irids, and Leguminosæ all assume it when they become ornithophilous, some reason must be shown why the simple explanation given by Darwin should be set aside while no other is offered."

THE WRITER OF THE NOTE.

CHELSEA BOTANIC GARDEN.

THE physic garden at Chelsea covers an area of between three and four acres. It stands by the side of the Thames at the east end of Cheyne Walk, opposite Battersea Park, a short distance west of Chelsea Hospital. On three sides it is inclosed by a high brick wall, and on the fourth you look through iron railings on to the Thames Embankment and the river. Within this area there are a dwelling-house, rooms for the gardeners, a large lecture-room, and four conservatories, and the rest is laid out in walks, flower-beds, and grassy interspaces. It is now too much surrounded by houses for trees to prosper, but one of the cedars of Lebanon planted in 1683 still survives. Amongst the others may be seen, or were until lately, well-grown examples of Oriental plane, Salisburia, Wistaria, hawthorn, black walnut, black mulberry, and many others. One of the most striking features of the garden is a large bed of yuccas on the north. It contains one of the finest collections of the different species and hybrids of rhubarb to be found anywhere in the country. The most valuable portion of its contents is a collection of between 300 and 400 hardy plants and shrubs, which are or have been used in medicine. These are arranged, shrubs and herbaceous plants intermixed, according to the system of Jussieu and De Candolle. There is a smaller collection arranged after the system of Lindley, who for many years directed the garden and gave the lectures. From these are sent up the plants which are required for the examinations which are held in the old hall of the Company near Blackfriars Bridge. Against the wall that flanks the garden on the east are nailed the fig and other tender shrubs, and beneath there is a narrow border containing Ferula, Verbascum, Acanthus, the fibre-yielding Chinese and Indian *Boehmeria nivea*, and a crowd of other herbaceous plants. In the centre of the garden there is a statue of Sir Hans Sloane, and a tank full of buckbean and water violet, surrounded by rockwork on which grow saxifrages, Hieracia, and spiny Astragali. South of the main walk that cuts the garden into two halves are beds full of non-medicinal plants, arranged in natural orders, another tank full of water lilies, bur-reeds, and bulrushes, and south of all have lately been laid out a couple of beds containing types of the twenty natural orders a knowledge of which is required for the elementary examination of the Science and Art Department. The present rainy season has suited the garden capitally, and during many years' acquaintance with it the writer of this article has never seen the herbaceous plants look more luxuriant than they do at the present time.

It would take up more space than we can spare to say even a few words about each of the distinguished botanists who have been connected with the garden. Here was laid the foundation of the classical "Gardener's Dictionary" of Philip Miller, which was first published in 1731, ran through eight editions in his life-time, has been translated into German, French, and Dutch, and formed the foundation and model of the many gardeners' dictionaries that have since been written. Amongst the well-known botanists of older date who were more or less connected with the garden, were Doody, Petiver, Hudson, Rand, and Alchorne, and in later times Lindley, Fortune, Thomas Moore, Curtis, Anderson, and David Don. Full particulars about all these will be found in Field's history of the garden, published in 1820, and a second edition, considerably enlarged, published by Dr. Semple in 1878.

The ground was originally taken by the Apothecaries' Company in 1673, as a spot on which to build a convenient house for their ornamental barge. In 1674 a wall was built round the open space, and the cultivation of medicinal plants commenced. At first the ground was rented, at a nominal sum, from Lord Cheyne, who was then lord of the manor of Chelsea. In 1712 the property was purchased by Dr. (afterwards Sir Hans) Sloane. In 1722, Sir Hans Sloane granted the use of the ground in perpetuity to the Apothecaries' Company at a yearly rent of £5, to the end, says the deed, "that the said garden may at all times hereafter be continued as a physic garden, and for the better encouraging and enabling the said Society to support the charge thereof, for the manifestation of the power, wisdom, and glory of God in the works of the creation, and that their apprentices and others may better distinguish good and useful plants from those that bear resemblance to them that are hurtful." If these conditions are not fulfilled by the Apothecaries, the garden reverts to the Royal Society on the same terms, and if they fail to fulfil them it falls to the College of Physicians. Under this deed the Society of Apothecaries has now held the garden for 170 years, during which time, of course, the land has greatly increased in value.

At the present time the garden is used for botanical purposes by four classes of students:—

Firstly, those who are going up for the preliminary examination of the Apothecaries' Company, in which materia medica is one of the principal subjects. This examination, we understand, is often taken by those who seek places as chemists and druggists, and who do not intend to proceed to the L.S.A. Secondly, the ladies who compete for the silver medal which has lately been offered annually by the Apothecaries' Company. Thirdly, pharmaceutical students. One of the largest private pharmaceutical schools is situated in the neighbourhood. Fourthly, students who are intending to go up for the botanical examinations of the Science and Art Department. For this there have been about 3000 entries per annum for many years, and 25 per cent. of the marks (30 per cent. being a second class pass) are allotted for a description of a plant and a diagnosis of its natural order. Probably we should be justified in estimating that a quarter of these 3000 candidates live in London, and cannot get living specimens to study without undertaking a railway journey, and of course it is only fair to assume that those who have passed their examination will continue to take an interest in the science, particularly as many of them teach botany in elementary schools. It is only the first and second of these four classes of students who have any direct claim on the Apothecaries' Company, but they have always construed liberally the "others" mentioned in Sir Hans Sloane's deed. Last year the number of admissions by students' tickets, as registered in the visitors' book, was 3000. A course of twelve lectures and demonstrations have been given for many years in summer by Mr. J. G. Baker, and at these the annual attendance ranges from 550 to 700, or an average of 50 or 60 students to each lecture.

The Society of Apothecaries have given no public intimation that they are dissatisfied with the present condition of things, but they bear the whole expense of keeping up the garden, and reap only a share of the benefit. A Committee has been appointed by the Royal Society to consider their position in the matter; and last week a meeting was held in the Town Hall at Chelsea, at which Lord Meath presided and Prof. Flower was one of the

speakers, at which the following resolution was passed: "That this meeting of the inhabitants of Chelsea, having heard that there is a probability of the old physic garden on the Chelsea Embankment being no longer kept up by the Apothecaries' Company, considers that every effort should be made to preserve it for the public as an open space." Under these circumstances we wish to put in a plea that the claims of the London students of systematic botany and materia medica should not be overlooked, or the scantiness of their opportunities for the study of living plants forgotten.

THE SEARCH FOR COAL IN THE SOUTH OF ENGLAND.[1]

(1) THE bare facts of the recent discovery of coal-measures at Shakespeare Cliff, near Dover, have been published in the press, and the full account cannot be written till the completion of the inquiry which is now going on. It is, however, not unfitting that the bearing of the discovery on the general question of the existence of workable coal-fields in Southern England should be discussed within these walls, not merely on account of its general interest, but because it naturally follows the paper read by Mr. Godwin-Austen before the Royal Institution, in 1858, "On the Probability of Coal beneath the South-Eastern parts of England." In 1855 he had placed before the Geological Society of London the possibility of the existence of coal in South-Eastern England at a workable depth. In the two years which had elapsed, "the possibility" had grown in his mind into the "probability," and in the thirty-two years which have passed between the date of the paper before this Institution and the present time, "the probability" has been converted into a certainty by the recent discovery at Dover. In this communication, the lines of the inquiry laid down by Godwin-Austen will be strictly followed. We must first examine the conditions under which the coal-measures were accumulated.

(2) The seams of coal are proved, by the surface-soil traversed by roots and rootlets, to which in some cases the trunks are still attached, to have been formed *in situ* by the growth and decay of innumerable generations of plants (*Lepidodendra, Sigillaria, Calamites*), pines (*Trigonocarpa, Dadoxylon, Sternbergia*) allied to *Salisburia*, and a vast undergrowth of ferns, all of which contributed to form a peat-like morass. Each seam represents an accumulation on a land-surface, just as the sandstones and shales above it point to a period of depression during which sand-banks and mud-banks were deposited by water. The fact also that the coal-seams in a given sinking are parallel, or nearly parallel, implies that they were formed on horizontal tracts of alluvium, while the marine and fresh-water shells in the associated sandstones and shales prove that they were near the level of the sea, or within reach of a mighty river. This tract of forest-clad marsh-lands, as Godwin-Austen and Prestwich have pointed out, occupied the greater part of the British Isles, from the Highlands of Scotland southwards as far as Brittany, and eastwards far away into the valley of the Rhine, and westwards over the greater part of Ireland. It swept round the hills of South Scotland and the Lake district and the region of Cornwall. It occupied a delta like that of the Mississippi, in which the forest-growths were from time to time depressed beneath the water-line, until the whole thickness of the coal-measures (7200 feet thick in Lancashire, 7600 in South Wales, and 8400 in Somersetshire) was built up. After each depression the forest spread again over the sand and mud of the submerged parts, and another peat-layer of vegetable matter was slowly accumulated above that buried beneath the sand and mud. The great extent of this delta implies the existence of a large river draining a large continent, of which the Highlands of Scotland and the Scandinavian peninsula formed parts, and which I have described before the Royal Institution under the name of Archaia.

(3) At the close of the Carboniferous age, this vast tract of alluvium was thrown into a series of folds by earth-movements. These have left their mark in the south of England and the adjacent parts of France, in the anticline of the English Channel, the syncline of Devonshire, the anticline of the Mendip Hills and of the lower Severn, and the syncline of the South Wales coal-fields. These great east and west folds have been traced from the south of Ireland on the west, through 35 degrees of latitude, through North France and Belgium, as far as the region of Westphalia. Next, the upper portions of the folds were attacked by the subaërial and marine agents of denudation over the whole of the Carboniferous area, leaving the lower parts to form the existing coal-fields which lie scattered over the surface of the British Isles, and are isolated from each other by exposures of older rocks; and a broad east and west ridge was carved out of the folded and broken Carboniferous and older rocks, extending from the anticline of the Mendip Hills eastward through Artois into Germany, and constituting the ridge or axis of Artois of Godwin-Austen.

The next stage in the history of the folded Carboniferous and older rocks is marked by the deposition of the Permian and Secondary rocks on their eroded and water-worn edges, by which they were partially concealed or wholly buried, and these newer strata thin off as they approach the ridge of Artois. This barrier, also, of folded Carboniferous and older rocks sank gradually beneath the sea in the Triassic, Liassic, Oolitic, and Cretaceous ages, and against it the strata of the first three named ages thin off, while in France and Belgium the Cretaceous deposits rest immediately upon the water-worn older rocks.

From these general considerations it is clear that the coal-measures which formerly extended over nearly the whole of Southern England can now only be met with in isolated basins under the newer rocks, and that these are thinnest along the line of the above-mentioned barrier.

(4) The exposed coal-fields in Britain, and on the Continent also, Godwin-Austen pointed out, along this line, are of the same mineral character, and the pre-Carboniferous rocks are the same. This ridge or barrier also, where it is concealed by the newer rocks, is marked by the arch-like fold (anticlinal) of the chalk of Wiltshire, and by the line of the North Downs in Surrey and Kent. Godwin-Austen finally concluded that there are coal-fields beneath the Oolitic and Cretaceous rocks in the south of England, and that they are near enough to the surface along the line of the ridge to be capable of being worked. He mentioned the Thames Valley and the Weald of Kent and Sussex as possible places where they might be discovered.

These strikingly original views gradually made their way, and in the next eleven years became part of the general body of geological theory. They were, however, not accepted by Sir Roderick Murchison, the then head of the Geological Survey, who maintained to the last that there were no valuable coal-fields in Southern England.

(5) The next important step in the direction of their verification was that taken by the Coal Commission of 1866-67, by whom Mr. Godwin-Austen was examined at length, and the results of the inquiry embodied in the Report by Mr. Prestwich. In the Report Mr. Godwin-Austen's views are accepted, and fortified by a vast number of details relating both to the coal-fields of Somersetshire and of France and Belgium. Mr. Prestwich also calls special attention to the physical identity of the coals of these two regions, and to the fact that the Carboniferous and older rocks in both are similarly dis-

1 Friday Evening Lecture delivered at the Royal Institution on June 6, by Prof. W. Boyd Dawkins, F.R.S.

turbed. He concludes, further, that the coal-fields which now lie buried beneath the newer rocks are probably equal in value and in extent to those which are exposed in Somerset and South Wales on the west, and in Belgium and France on the east.

We will now proceed to test these theoretical conclusions by the light of recent observations.

(6) The coal-fields of Somerset and Gloucester were proved by the labours of Prof. Prestwich and the Coal Commission of 1866–67 to be small fractions of the great coal-basin which lies buried beneath the Triassic, Liassic, and Oolitic rocks, from the Mendip Hills northwards past Bristol to Wickwar. On the west also three small isolated coal-basins occur—those of Nailsea and Portishead, which are partially, and that of Aust, which is wholly, concealed by the newer rocks. The coal-measures are folded and broken, and traversed by great "overthrust" faults, which at Kingswood give the same series of coals twice over in the sinkings of one colliery. Their southern boundary is the line of the Mendip Hills. They also probably occur at a depth which remains to be proved, still further to the south, in the valley of the Axe and the district of Glastonbury, the most southern boundary being the mountain limestone of Cannington, near Bridgwater. The great Somerset and Gloucester field may extend to the east under the newer rocks, between Freshford and Beckington, in the district south of Bath.

The value of the evidence of the coal-fields of the west of England on the general question consists in the fact that they may be taken as fair samples of those which lie concealed along the line of the buried ridge through South-Eastern England in the direction of France, Belgium, and Germany.

(7) One of these concealed coal-fields has been struck in a deep boring at Burford, near Witney, in Oxfordshire, at a depth of 1184 feet, under the following rocks:—

	Feet.
Oolites	148
Lias	598
Rhætic	10
Triassic rocks	428

The sandstones and shales of the coal-measures were penetrated to a depth of 225 feet (De Rance, Manch. Geol. Soc., March 26, 1878).

These coal-measure rocks form, as suggested by Hull, one of the same series of coal-basins as those of South Wales and the Forest of Dean, and probably mark the line of the continuation of the South Wales syncline in the direction of Harwich, where Carboniferous shale has been struck at a depth of 1052 feet from the surface.

This boring proves not merely the presence of coal-measures at a workable depth in Oxfordshire, but also the important fact that the Triassic rocks, which are of great thickness further north, have dwindled down to an unimportant thickness in their range southwards and eastwards. Further, that south, in the London area, these rocks are wholly absent; and farther to the east, at Harwich, the Liassic and Oolitic strata and Lower Greensand are absent, and the Gault rests on the eroded Lower Carboniferous rocks, inclined at a high angle.

(8) The water-worn surface of the folded rocks, which are older than the Carboniferous, has been repeatedly struck in deep borings for water in the neighbourhood of London, at depths ranging from 839 feet at Ware to 1239 feet at Richmond. They consist of Silurian strata in the north at Ware, and of Old Red Sandstone or Devonian rocks in the other localities. From their high angle of dip, as in the case of similar rocks underlying the coal-fields of Somerset and Northern France and Belgium, it may be inferred that coal-fields lie in the synclinal folds in the neighbouring areas.

From the fact of the Silurian rocks being in the north, while all the rest of the borings to the south terminate in the Devonian or Old Red rocks, it may be inferred that the chalk of the North Downs probably conceals the coal-measures. It must also be noted that there are no Wealden rocks in the London area, and no Lower Greensands, and that the Lower Oolites at their thickest are only 87 feet. The secondary rocks, which are of great thickness in the midland and northern counties, thin off as they pass southwards towards London, against the ridge of older rocks, as both Austen and Prestwich have pointed out.

It is therefore in the area south of London, rather than in that immediately to the north, that the coal-measures are to be looked for at a workable depth beneath the surface, and underneath the chalk of the North Downs. It must, however, be noted that the line of the South Wales syncline through Burford passes to the north of Ware, and that there may be coal-measures in the northern parts of Essex and of Hertfordshire at a workable depth.

(9) The Report of the Coal Commission was published in 1871, and in the following year the Sub-Wealden Exploration Committee was organized by Mr. Henry Willett, to test the question of the existence of the Carboniferous and pre-Carboniferous rocks in the Wealden area by an experimental boring. The site chosen was Netherfield, about 3 miles south of Battle, in Sussex, where the lowest rocks of the Wealden formation constitute the bottom of the valley. The rocks penetrated were as follows:—

Section of Netherfield.

	Feet.
Purbeck strata...	200
Portland strata	57
Kimmeridge clay	1073
Corallian strata	515
Oxford clay	60
	1905

This boring showed that the coal-measures and older rocks are, in that region, more than 1900 feet from the surface of the ground. We may also infer, from the fact of the bottom of the bore-hole being in the Oxford clay, and from the known thickness of the Bath Oolitic strata in the nearest places, that it lies buried beneath considerably more than 2000 feet of newer rocks. With this valuable, though negative result, the Sub-Wealden exploration came to an end. It was a purely scientific inquiry, paid for by subscription, and largely supported by those who had no pecuniary interest in the result.

The experience of the boring at Netherfield showed that the search for the coal-measures and older rocks of Godwin-Austen's ridge would have to be carried out at some spot further to the north, in the direction of the North Downs. In the district of Battle the Oolitic rocks were proved to be more than 1700 feet thick, and the great and increasing thickness of the successive rocks of the Wealden formation above them, which form the surface of the ground between Netherfield and the North Downs, rendered it undesirable to repeat the experiment within the Wealden area proper, where the Wealden rocks presented a total thickness of more than 1000 feet, in addition to that of the Oolites. My attention, therefore, was directed to the line along the North Downs, where Godwin-Austen believed that the Wealden beds abruptly terminated against the ridge of coal-measures and older rocks, and where, therefore, there would be a greater chance of success.

(10) The evidence, also, of the French, Belgian, and Westphalian coal-fields pointed in the direction of the North Downs.

The Carboniferous and older rocks, which we have hitherto traced only as far as the area of London from their western outcrops in Somerset, Gloucestershire, and South Wales, reappear at the surface in Northern France,

Belgium, and Westphalia, and contain most valuable coal-fields, which are long, narrow, and deep. These extend from the district of the Ruhr on the east, through Aachen, Liége, Namur, Charleroi, Mons, and Valenciennes. The enormous value of the last field led, during the last hundred years, to numerous borings through the newer rocks, which have extended the western range of the coal-measures upwards of 95 miles away from its disappearance under the Oolites and chalk, as far as Flechinelle, south of Aire, or to within 30 miles of Calais. It occupies throughout this distance a narrow trough or syncline, 11 miles across at Douchy, and about half a mile at its western termination. It is represented still further to the west by the faulted and folded coal-fields of Hardinghen and Marquise, which are within about 12 miles of Calais. The coal-measure shales and sandstones found in a boring at Calais, at a depth of 1104 feet from the surface, in 1850,[1] reveal the existence of another coal-field in the same general line of strike, and making for Dover and the North Downs.

(11) We have seen that the range of the coal-measures has been pushed farther and farther to the west by experimental borings, until they have been proved to exist underneath Calais. The opposite shores of the Straits of Dover, therefore, presented the best locality for a trial still further to the west. In choosing a site, the Channel Tunnel works, close to Shakespeare Cliff, Dover, appeared to me to present great advantages, which I embodied in a report to Sir Edward W. Watkin, in 1886. The site is within view of Calais, and not more than 6 miles to the south of a spot where about 4 cwt. of bituminous material was found embedded in the chalk in making a tunnel, which, according to Godwin-Austen, had been probably derived from the coal-measures below.

Prestwich also had pointed out, in 1873, in dealing with the question of a tunnel between England and France, that the older rocks were within such easy reach at Dover, that they could be utilized for the making of a submarine tunnel. Sir Edward Watkin acted with his usual energy, and the work was begun in 1886, and has been carried on down to the present time, under my advice, and at the expense of the Channel Tunnel Company. The boring operations have been under the direction of Mr. F. Brady, the Chief Engineer of the South-Eastern Railway, to whose ability we owe the completion of the work to its present point, under circumstances of great difficulty. A

shaft has been sunk (A, Fig. 1) on the west side of the Shakespeare Cliff, close to the shaft of the Channel Tunnel (B) to a depth of 44 feet, and from this a bore-hole has been made to a depth of 1180 feet.

Coal-measures, sandstones, and shale sand clays, with one seam of coal	70

The coal-measures were struck at a depth of 1204 feet from the surface, or 1160 feet from the top of the bore-hole, and a seam of good blazing coal was met with 20 feet lower.

(12) This discovery proves up to the hilt the truth of Godwin-Austen's views as to the range of the coal-measures along the line of the North Downs, and as to the thinning off of the Oolitic and Wealden strata against the buried ridge. The former are less than one-third of their thickness at Netherfield, and the latter are wholly unrepresented. It establishes the existence of a coal-field in South-Eastern England, at a depth well within the limits of working at a profit. The principal coal-pits in this country are worked at depths ranging from over 1000 to 2800 feet, and one at Charleroi, in Belgium, is worked to a depth of 3412 feet.

The Dover coal-field probably forms part of the same narrow trough as the Calais measures, prolonged westward under the Channel further to the south than Godwin-Austen drew it in 1858. Whether it is a trough similar to that which extends through Northern France for more than 100 miles from east to west, as Godwin-Austen has drawn it in the diagram on the wall, reaching as far to the west as Reading, or whether it is a small, faulted, insignificant fragment of a field, such as that of Marquise and Hardinghen, remains to be proved. It is,

[1] This fact is doubted by Gosselet. I am, however, informed by Prestwich that both he and Élie de Beaumont identified them as coal-measures at the time, and I see no reason for doubting the accuracy of those two eminent observers. The cores were, unfortunately, lost in the first Paris Exhibition.

however, one of a chain of coal-fields which will, in my opinion, ultimately be proved to extend under the newer rocks between Dover and Somerset, along the line of the North Downs, in long narrow east and west troughs. It is probably a continuation beneath the Straits of Dover of the coal-measures struck at Calais (see Fig. 2).

The further question as to the value of these fields may be answered by the amount of coal in the fields which are now being worked in Westphalia, Belgium, France, and Somersetshire. The Westphalian coal-field contains 294 feet of workable coal, distributed in 117 seams; that of Mons, 250 feet, in 110 seams; and that of Somerset, 98 feet, in 55 seams. The North French coal-field in 1887 yielded 7,119,633 tons, and gave employment at the pits to 29,000 men, and is rapidly increasing its output.

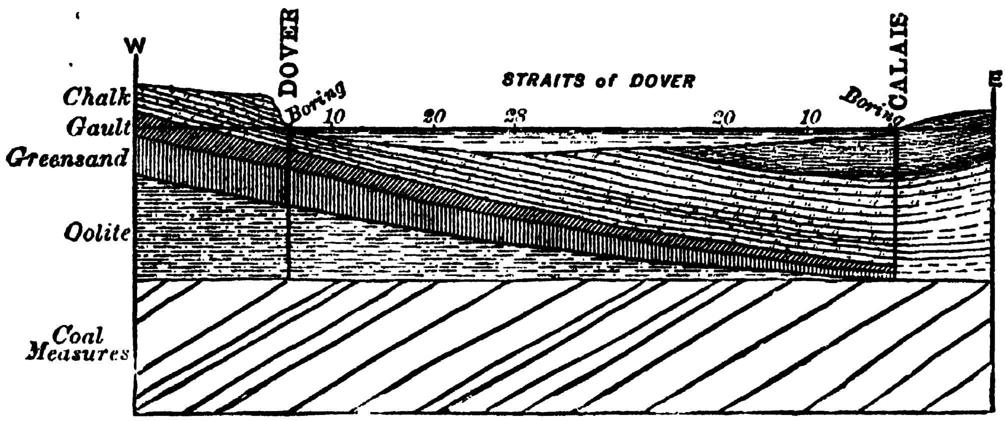

FIG. 2.—Probable Range of Coal-measures between Dover and Calais.

It may be inferred that the buried coal-fields which await the explorer in the North Downs are in all probability not inferior to these. Godwin-Austen, in his memorable paper before the Geological Society, in 1855, said that if one of these buried fields were once struck in South-Eastern England, their exploration would be an easy matter. It has been struck at Dover, and the necessary base is laid down for further discoveries, which in all probability will restore to South-Eastern England the manufactures which have long since fled away to the coal districts of the west and north, and which will put off by many years the evil day when the energy stored up in the shape of coal in these islands shall have been spent.

RECENT ADDITIONS TO THE LITERATURE OF INSULAR FLORAS.

THE LACCADIVES.

THESE small islands, fourteen in number, are situated between 10° and 14° N. lat., and at 120 to 180 miles from the Malabar coast of India. They are of coral formation, almost without exception portions of atoll rings, and nowhere elevated more than twenty feet above the sea, so that storm-waves sometimes sweep completely over them. In 1847 such a wave destroyed 1000 of the small population, and there have been equally disastrous cyclones in much more recent times. Indeed, according to Hunter's Imperial Gazetteer of India, the islands, which have an area of two to three square miles, are nowhere more than ten or fifteen feet above the level of the sea. In 1871 the population was estimated at about 13,500, and the almost sole cultivation is the coco-nut palm. It is supposed that the abundance of this palm may have attracted the first settlers, but as that event occurred more than 350 years ago—how much more it is impossible to say—this point must remain uncertain. The total annual value of the exports, consisting almost entirely of the products of the coco-nut palm, is said to be about £17,000. From the physical character of the group, it was not expected that the flora contained any endemic element, but until quite recently there was no published account of the vegetation, beyond broad generalizations. Dr. D. Prain, Curator of the Calcutta Herbarium, has supplied the want in the "Memoirs by Medical Officers of the Army of India," Part V., where he gives an enumeration and analysis of all the plants hitherto known by him to have been collected in the islands, and he has since communicated to the writer a list of some twenty additional species. Briefly, the vegetation consists, apart from cultivation, of very widely dispersed plants—whose wide area is due to ocean currents, birds, or winds—plus a number of weeds of tropical cultivation. Dr. Prain has not visited any of the islands himself, and collectors have not concerned themselves with the question of colonization of plants from drift-seeds or from seeds conveyed to the islands by carpophagous birds; hence his deductions are mainly based on probabilities, which he discusses in considerable detail, followed by a table giving the full distribution of all the plants then known to him from the islands. These number eighty, including seventeen purely cultivated plants. It is interesting to know what is cultivated, of course; but it is undesirable to encumber the distributional tables with plants of this category. Dr. Prain estimates that the presence of eleven species is certainly due to the sea, seventeen probably so, and twenty-two possibly so; whilst birds are regarded as the agents in two, three, and five instances respectively. The two ferns collected in the island of Anderut are set down with certainty to the wind, and two or three other plants probably to the same agency. The rarity of ferns seems to be accounted for, in part at least, by the extreme flatness of the islands rather than by unfavourable conditions, for Dr. Treub found eleven species of ferns on the elevated part of Krakatão only three years after the great eruption, which absolutely destroyed all the vegetation previously existing, and covered the island with a volcanic deposit of intense heat from one to sixty yards in thickness.

One common tree in the vegetation of many islands of the Indian Ocean we miss in Dr. Prain's list, and that is *Cordia subcordata*, the iron-wood of the Keeling Islands.

THE KURILES.

Mr. Kingo Miyabe, lately appointed Professor of Botany at the Agricultural College, Sapporo, Japan, and formerly a student at Harvard, U.S., and for a short time in this country, is the author of a "Flora of the Kurile Islands," which is published in the Memoirs of the Boston [U.S.] Society of Natural History, vol. iv., No. 7.

This is perhaps the most finished piece of systematic and geographical botany yet published in English by a Japanese botanist, and it will give the author a reputation for completeness and conciseness that might be envied by many western botanists. The enumeration is based partly on personal observation and partly on scattered records and herbarium specimens, for which full references are given; and all authorities are cited, so that the sources of information are not uncertain, as is too often the case.

The Kurile Islands form a chain nearly 800 miles long, extending from the southern point of Kamtschatka to Yezo; and, by treaty with Russia in 1875, they are now all under Japanese rule. The principal islands are about twenty-four in number, but they are only partly inhabited, on account of their barrenness and lack of good water. The whole chain is described as of volcanic origin, and fifty-two cones have been observed, seventeen of which were active. The coasts generally are precipitous and unapproachable, and the few bays and coves they possess are insufficiently sheltered to be safe for ships in bad weather. Indeed, some of the islands can only be visited in the perfectly calm weather of the summer-time. In consequence of the sea-currents from the north, the climate is very cold for the latitude (about 43° to 51°), and dense fogs prevail during easterly or southerly winds. There is, however, a marked difference in the climate of two or three of the southern islands, which come under the influence of a warm current running to the north-east. North of Etorofu the islands are locked in ice from November till April or May, and the mountains are snow-capped throughout the summer; hence it is not surprising to learn that the vegetation is of a sub-arctic character.

Mr. Miyabe's enumeration comprises 299 species of flowering plants, and 18 vascular cryptogams; but it is not supposed that these numbers exhaust the flora. These 317 species belong to 187 genera and 53 natural orders, and 21 of the latter are represented by a single genus, and 9 by a single species each. The natural orders comparatively rich in genera are: Compositæ, 15; Rosaceæ and Liliaceæ, 12; Gramineæ, 11; Ranunculaceæ and Ericaceæ, 8; Cruciferæ and Umbelliferæ, 7; and most of these orders are the richest in species, though the Caryophyllaceæ and Scrophulariaceæ come in before the Cruciferæ and Umbelliferæ. The Compositæ number 30 species; the Rosaceæ, 23; the Gramineæ, 17; and the Ericaceæ, 16. It is noteworthy that in this small flora, or, rather, portion of a flora, the Compositæ form a relatively high percentage, as they do in the Arctic flora and in the various regions of Central and Eastern Asia, from the Caspian to Japan, whose floras have been analyzed by Maximowicz. So far as at present known, the Kurile flora contains no endemic element, unless we except two imperfectly-known plants, which, however, as Mr. Miyabe observes, are much more likely to be forms of more widely-spread species. North of the islands mentioned as under the influence of a warm sea-current, the flora is largely composed of species having a wider range, many of them all round the northern hemisphere, and species having a more or less wide area in North-East Asia. The facts that upwards of 25 per cent. of the species are British, and that 84 per cent. of the genera are spread over Europe, Northern Asia, and North America, will assist us in forming an idea of the general composition of the vegetation. Only three of the genera are restricted to the mountains of tropical Asia and North-Eastern Asia—namely, *Skimmia*, *Crawfurdia*, and *Acanthopanax*. Mr. Miyabe finds that 26 per cent. of the species are American-Asiatic; and 10 per cent. of these reach Eastern North America. Only six genera occur which do not reach Japan—namely, *Parrya*, *Tetrapoma*, *Claytonia*, *Lupinus*, *Armeria*, and *Dodecatheon*.

The existence in the southern islands, Kunashiri and Etorofu, of such plants as the following is strong evidence of a warmer climate: *Dianthus superbus*, *Hypericum erectum*, *Skimmia japonica*, *Ilex crenata*, *Rhus Toxicodendron*, *Hydrangea scandens*, *Aralia racemosa*, *Acanthopanax ricinifolia*, *Crawfurdia japonica*, and *Bambusa Kurilensis*. The bamboo is said to grow so thick and so tall in the neighbourhood of Shana, in Etorofu, as to form almost impassable thickets.

Mr. Miyabe concludes his discussion of the flora of the Kuriles in the following words:—"From these observations I agree with Prof. Milne in the opinion that, at the time of the last great southerly migration of the rich polar flora, Japan received her portion mostly through the island of Saghalin, and but little, if any, through the then uncompleted chain of the Kurile Islands."

THE BAHAMAS.

A provisional list of the plants of this chain of islands, by John Gardiner and L. J. K. Brace, edited by Prof. C. Dolley, appears in the Proceedings of the Academy of Natural Sciences, Philadelphia, 1889, pp. 131–426.

This is not intended as a critical review, and perhaps an avowed provisional list is, in a sense, exempt from such an ordeal; yet it seems no more than right to call attention to the extraordinary notes and remarks under some of the species, genera, and orders, so that the writer who is responsible for them may have the opportunity of claiming all the credit due to him. Taking the first of the dicotyledons, *Clematis Vitalba*, it is said to be "indigenous and nearly cosmopolitan"; and *Delphinium* sp. is recorded as "indigenous from old world," whatever that may mean. The Bixineæ, "as a whole, have fully bitter and astringent properties, and some of the members are poisonous." This is indefinite, but the Compositæ are described as "plants mostly possessing a bitter principle which renders them tonic"; and *Eupatorium* (a genus of about 500 species) "is extensively used as a remedy for malaria." A more definite statement, "grasses are valuable as food for cattle and men," is true, although the instances on record of men having eaten grass itself are exceedingly rare. Some of the remarks on the distribution of the plants enumerated, and really restricted to the West Indian region, or the West Indian and Mexican regions, are equally incomprehensible. Thus *Alvaradoa amorphoides*, a shrub inhabiting the Bahamas, Cuba, and Mexico, including the interior province of Chihuahua in the north, is said to be found on "all tropical coasts." The work abounds in indefinite, and often unintelligible, remarks on the medicinal properties of plants. Under *Clethra tinifolia* we find the note: "This plant does not appear to be of use for anything. The order [Ericaceæ] has astringent properties. Its leaves and flowers are used as a diaphoretic; they are saponaceous and detergent."

The list itself is largely compiled from Grisebach's "Flora of the British West Indies," and from names communicated from Kew to Mr. Brace, based on specimens supplied by him from time to time; and is so far approximately correct. On the other hand, some of the additional names are strangely inaccurate and far-fetched Thus, *Sinapis Brassicata*, Linn., a Chinese plant, now believed to be the same as *S. juncea*, is put down as mustard, and as native of the West Indies. It is true that Grisebach uses this name in his "Flora of the British West Indian Islands," therefore it is, to that extent, excusable. That an "M.D." and a Professor of Biology should be so careless of his reputation as to publish such undigested matter is inconceivable. Apart from its faults, the list is imperfect so far as our present knowledge goes, and it may be better to await an emended edition before attempting to give any particulars of the flora here.

FERNANDO NORONHA.

Darwin landed on this island on the outward voyage of the *Beagle*, and collected a few plants, and Moseley succeeded in obtaining specimens of a few plants from the main island and the islet of St. Michael's Mount, but was prevented from making a complete collection in consequence of the *Challenger* being unprovided with the necessary authorization. These plants were described by the writer, and some of them figured in the "Botany of the *Challenger* Expedition." Provided with funds by the Royal Society, Mr. H. N. Ridley, formerly of the British Museum, and now Government Botanist for the Straits Settlements, visited the island in the summer of 1887, accompanied by Mr. G. A. Ramage and the Rev. T. S. Lea. The party remained on the island, or rather group, for there are several islets besides the main island, forming a chain, which may have formerly been continuous. Thus they had time to explore thoroughly the natural history; and an account of the botany, by Ridley, has just appeared in the current volume of the Journal of the Linnean Society. The singularly unconnected form of the introductory matter is doubtless due to the hurried manner in which it had to be completed before the author's departure for Singapore.

Fernando Noronha is in about 3° 50′ S. lat., and nearly 200 miles from the nearest point of the Brazilian coast. The whole chain is about eight miles in length, and the main island five miles long and nearly two miles across in one part, though very much narrower generally.

The fragment of the flora published in the "Botany of the *Challenger*" was considered sufficient to enable us to form an opinion of its general character, and state that there was no peculiarly insular element in the vegetation. This is fully borne out by the subsequent discoveries.

Mr. Ridley gives no analysis of the composition of the flora beyond classifying the plants as weeds, such plants as might be introduced by sea-currents, and such as have berries and eatable seeds, with examples; but he does not tabulate the whole. His very brief "summary" follows:—

"The whole group of islands possesses certain characteristics common to all truly oceanic islands and some of those which are merely the relics of vanished continents. In the first place there is the absence of indigenous mammals, and more noticeably of bats, of fresh-water fish, and amphibians. Again, the number of indigenous species, both of plants and animals, is very small, while the number of individuals is very large. The insects are small and dull in colour, and but few of the plants have showy flowers, white and yellow being prevailing colours. A considerable proportion of the indigenous plants are shrubby or arboreous, as in many other oceanic islands; but arboreous or even shrubby Compositæ do not exist, indigenous species of the order being rare in the group."

There will be differences of opinion, of course, as to the teachings of the data collected by Mr. Ridley and his companions, especially as to whether the present vegetation be a remnant of a former continental flora or a purely derived insular flora of comparatively recent origin.

Mr. Ridley himself states "that there is no evidence whatever to show a former connection with the mainland of Brazil at any time, in spite of what has been asserted by Dr. Rattray to the contrary." On the other hand, in a sketch of the geology of the island, based on petrological notes by Thomas Davies, which follows the enumeration, it is merely doubted "that the evidence is sufficient to prove a connection."

It appears, too, that "some American petrologists, who have found similar rocks to those of Fernando Noronha in the neighbourhood of Cape San Roque, seem to consider that 'the group may have been connected at one time with the mainland at this point."

Roughly counting the plants in the enumeration, we find there are nearly two hundred species of phanerogams, including weeds and a few others undoubtedly introduced, intentionally or unintentionally, by man. Out of this total, about thirty-two are described as new, or, in about half-a-dozen instances, more fully described than was possible from the imperfect material previously known. So far as present evidence goes, these are all endemic in Fernando Noronha; but while so much remains to be done in the investigation of the Brazilian flora, it should not be assumed that they are really so. Some of them, indeed, are admittedly very closely allied to previously-described species, and botanists might differ as to the propriety or expediency of treating the majority of them as independent species. And as to the whole, they present no peculiar characteristic suggesting the improbability of their occurring on the mainland.

The poverty of the flora in species may be largely due to climatal and other conditions. The climate is so dry generally, or the periods of drought are so protracted, that marsh plants, epiphytes, and ferns are almost wholly wanting. Mr. Ridley discovered one fern, *Pellæa geraniæfolia*, but it was rare and local, and this very widely-spread fern will grow in comparatively dry situations.

A large number of the plants, including several of the supposed endemic species, bear edible fruits; yet "there is only one fruit-eating bird on the island, and that is the endemic dove, *Zenaida noronhæ*." This fact tempts Mr. Ridley "to wonder whether the number of endemic species with edible fruit could possibly have all been introduced by this single species of dove, or whether other frugivorous birds may not at times have wandered to the shores." This sentence can hardly convey what Mr. Ridley had in his mind when he wrote; and being so distant from home he probably had no opportunity of revising it in print. Moreover, it is hardly correct to designate this group of islands as "oceanic."

Prominent in the vegetation among the assumed new or endemic plants are: *Erythrina aurantiaca*, *Cereus insularis*, *Bignonia roseo-alba*, *Pisonia Darwinii*, *Sapium sceleratum*, and *Ficus noronhæ*. There are also described two species of *Oxalis*, three of *Ceratosanthes*, a genus of Cucurbitaceæ, a *Sesuvium*, a *Cuscuta*, a *Physalis*, a *Solanum*, a *Lantana*, and three of *Cyperus*, besides a few others of less familiar genera. Of greater botanical interest is an apparently diœcious Combretacea, provisionally placed in *Combretum* as the type of a new section, *Terminaliopsis*. Taken as a whole, the vegetation is quite that of the mainland deprived of the moisture-loving element.

In conclusion, it may be stated that the woods mentioned by the earlier writers have almost disappeared since the main island has been made a convict settlement.

W. BOTTING HEMSLEY.

THE BRONTOMETER.

FOR more than a century meteorologists have been puzzled by the exceptional action of the barometer during some (not all) thunderstorms, and during some (but not all) heavy rains. As a general rule, one expects the barometer to fall for rain and bad weather, but in 1784 Rosenthal pointed out that "when a thunderstorm approaches the place where a barometer is situated, the mercury in the tube begins to rise; the nearer the thundercloud comes to the zenith of the observer, the higher does the mercury rise, and reaches its highest point when the storm is at the least distance from the observer. As soon, however, as the cloud has passed the zenith, or has become more distant from the observer, the weight of the atmosphere begins to decrease and the mercury to fall."

The recent rapid increase in the number of self-recording barometers in use has led to much interest being taken in these fluctuations, which are sometimes very

numerous, and far from the simple rise and fall noted by Rosenthal, Planer, Toaldo, and other early writers. A very good illustration was afforded by my Redier barograph on August 2-3, 1879, of which the curve is reproduced below.

It might for a moment be supposed that the zig-zag about 2 a.m. was due to what is known as "pumping" in the barometer, but that is not the case. "Pumping" rarely takes a minute from its lowest to its highest point, *i.e.* two minutes from one maximum to another,[1] whereas these maxima are at intervals of about half an hour.

Camden Square, London, August 1879.

Several explanations of these oscillations have been offered, and in my paper in the Proc. Roy. Soc. I have endeavoured to give a summary of them, but I have long felt that as a preliminary to a theory we ought to be sure of the facts.

Years ago, when Sir Francis Ronalds, F.R.S., had his collection of electrometers in the dome of Kew Observatory, he devised what he called a storm clock, which was really a paper going at a regular rate, so that the observer needed only to record the phenomena, and the position of his writing showed the time.

In 1890 we ought to do better than half a century ago, and, thanks to the great skill of MM. Richard Frères, of Paris, the new machine, if it does not absolutely justify its name "brontometer" (Βροντή μέτρον, thunderstorm measurer), is a very near approach to it.

And first as to the object, we want to find out (1) the nature of the oscillations already mentioned; and (2) to what they are due.

The only way to do this is to get them on so large a scale that they can be critically examined, and to find out with what phenomena they are synchronous, or in definite relation as to sequence and time. Irrespective altogether of these barometric oscillations there are several features in thunderstorms not at all understood, such, for instance, as whether the rush of rain which sometimes accompanies an exceptionally fine flash of lightning is the cause or the result of that flash. For this and other points absolutely accurate time is of the highest importance, and evidently all phenomena must be recorded on one sheet of paper.

A method adopted for some of his instruments by Mr. H. C. Russell, F.R.S., of Sydney, might with advantage be copied in some of the European Observatories. As a general rule, and for ordinary phenomena, half an inch of paper for an hour of time, *i.e.* 12 inches per diem, gives a sufficiently open scale; but when special phenomena occur it is very handy to be able to accelerate the speed five or ten times, and this Mr. Russell does with ease. But even ten times times the ordinary speed, or 5 inches an hour, would not enable one to read closer than to quarter minutes, which would be useless for ascertaining the details of a thunderstorm and the correlation of the various phenomena with the peculiar oscillations already mentioned.

These, then, are some of the reasons which led me, more than three years since, to consult MM. Richard as to the construction of the brontometer, now at length completed.

It is provided with endless paper, 12 inches wide, travelling under the various recording pens at the rate of 1·2 inch per minute, or 6 feet per hour. This is about 150 times faster than is usual in meteorological instruments, and enables the time of any phenomenon to be read off with certainty to a single second of time.

The traces are made in aniline ink by a series of seven Richard pens.

The first pen is driven by the clock which feeds the paper, so that the time scale and the paper must go together. The pen usually produces a straight line, which serves as the base line for all measurements, but at 55 seconds after each minute the pen begins to go, at an angle of about 45°, one-tenth of an inch to the left, and at the sixtieth second it flies back to its original position.

The second pen is driven by one of Richard's anemocinemographs—a name which they have given to a pattern of anemometer not yet known in England. The external portion has some resemblance to the ordinary windmill governor, but it differs from it in that the plates are curved, not flat; they are made of aluminium, and are so light that they have little momentum, and have thus a great advantage over cups, which run on for many seconds after the wind-force has decreased or ceased. The fans make one revolution for each metre of wind that passes, and send an electric current to the brontometer, where it acts on an electro-magnet, and tends to draw this (second) pen towards the left; but a train of clock-work is constantly tending to draw the pen to the right, the joint result being that the pen continuously shows, not the total motion (as is the case with most anemometers), but the actual velocity almost second by second. It does this certainly with an error of less than five seconds, for the fans will stop dead in less than that time, and the clock-work train will bring the pen from indicating a velocity of 70 miles an hour to 20 miles an hour in three seconds, and down to a dead calm in seven seconds. The trace will thus resemble that of a pressure anemometer, but with a much more open scale than was ever before available.

The third pen is actuated by a handle, and can be set at zero or at 1, 2, 3, or 4 spaces from it. The author's

[1] I believe that half a minute would be nearer, but until the brontometer has been worked during a heavy gale no one knows.

original idea was, partly by watching a storm-rain-gauge, and partly by estimation, to decide on the intensity of the rain, and to indicate that intensity by moving the pen further and further from zero as the fall becomes heavier. Experience alone will show whether that is, or is not, superior to moving it one step for each $\frac{1}{100}$th of an inch of fallen rain, which can be done by making a Crosley rain-gauge send a current into the room where the brontometer is placed, and strike a bell there. In a heavy storm there will, however, be so much for the observer to do, that very probably count would be lost. It may, therefore, be necessary to make it act automatically.

The fourth pen is actuated somewhat like a piano. On the occurrence of a flash of lightning, the observer presses a key, the pen travels slightly to the right, and flies back to zero. Referred to the automatic time-scale, this gives, to a second, the time at which the key was depressed.

The fifth pen is similar, but, being intended to record the thunder, the observer will continue to hold down the key until the roll is inaudible. The time of the departure of this pen from zero will evidently be later than that for the lightning by the time-interval due to the distance of the flash, and possibly something may be learned from the accurate record of the duration of the thunder.

The sixth pen is similar to the third, and is intended to record the time, duration, and intensity of hail.

The seventh and last pen is devoted to an automatic record of atmospheric pressure. As the rapid motion of the paper, which is indispensable for studying the details of a thunderstorm, has enlarged the time-scale more than a hundredfold, it was imperative that the barometric scale should itself be greatly enlarged. But the range of the barometer in London is more than 2½ inches, and no enlargement less than ten times the natural (mercurial) scale would be of any use; hence a breadth of 25 inches of paper would be necessary, unless some mode of shifting the indication could be devised.

Several plans were tried, but finally a modification of Richard's statoscope has been adopted, which is so sensitive that it will indicate the opening or shutting of a door in any part of the house, gives a scale of 30 inches for each mercurial inch (*i.e.* about three times that of a glycerine barometer), and yet only requires 4 inches breadth of the brontometer paper. Without entering into all the details of construction, it is desirable to explain the general principle, and its application. As it was essential that the apparatus should record accurately to 0·001 inch of mercurial barometric pressure, it was evident that friction had to be reduced to a minimum, and considerable motive power provided. This is done by placing in the base of the brontometer a galvanized iron chamber, which contains about 3½ cubic feet of air; on the upper part are a series of elastic chambers, similar to the vacuum boxes of aneroid barometers, but much larger. When the instrument is to be put in action, these chambers are connected with the large air-chamber, and a tap is closed which shuts off communication with the external air. Any subsequent increase, or decrease, of atmospheric pressure will compress, or allow to dilate, the air in these chambers, and the motion of the elastic ones produces that of the recording pen.

Obviously, any large change in the temperature of the confined air would vitiate the readings; but (1) the instrument is not required to give absolute, but merely differential, values, and (2) the influence of the changes of temperature is greatly reduced by the chamber being surrounded with 4 inches thick of non-conducting material, besides nearly 1 inch of wood outside of it. The change of temperature in a room, and during the short time that the statoscope will be worked without resetting to zero (*i.e.* without opening the tap) has not hitherto produced any measurable effect.

G. J. SYMONS.

NOTES.

THE Société de Physique et d'Histoire naturelle de Genève has decided to celebrate its hundredth anniversary. It was founded in 1790, having originated in informal meetings of eminent men of science who lived at that time in Geneva. On October 23 a special meeting will be held, at which papers will be read relating to the history of the Society and to the labours of its members. It is hoped also that some honorary members may be disposed to contribute to the success of the meeting by sending scientific communications. In the evening there will be a banquet. Members who intend to be present are asked to write to M. de la Rive, the President, some days before the celebration.

THE International Exhibition of Mining and Metallurgy, at the Crystal Palace, was officially opened on Monday by Lord Thurlow, F.R.S., one of the honorary vice-presidents of the Exhibition. We shall give some account of the Exhibition when the arrangement of the specimens is in a more forward state.

THE British Medical Association is holding its fifty-eighth annual meeting at Birmingham. The President, Dr. Willoughby F. Wade, delivered the opening address on Tuesday. On Wednesday Sir Walter Foster delivered an address in medicine; to-day Mr. Lawson Tait delivers an address in surgery; and to-morrow, at the concluding general meeting, Dr. W. H. Broadbent will speak on therapeutics. At the meeting to-day the Association's gold medal "for distinguished service" will be presented to Surgeon Parke, of the Emin Relief Expedition.

THE summer meeting of the Institution of Mechanical Engineers is being held at Sheffield. It began on Tuesday, July 29, and will not be concluded until to-morrow. The following is a list of the papers: on steel rails, considered chemically and mechanically, by Mr. Christer P. Sandberg, of London; on recent improvements in the mechanical engineering of coal-mines, by Mr. Emerson Bainbridge, of Sheffield; description of the Parkgate iron and steel works, by Mr. Charles J. Stoddart, managing director; description of the Sheffield water works, by Mr. Edward M. Eaton, engineer; description of the Loomis process of making gas for fuel, by Mr. R. N. Oakman, Jun., of London; on milling cutters, by Mr. George Addy, of Sheffield; on some different forms of gas furnaces, by Mr. Bernard Dawson, of Malvern; on the Elihu Thomson electric welding process, by Mr. W. C. Fish, of London (communicated through Prof. Alexander B. W. Kennedy, F.R.S., Vice-President).

THE Leeds Executive Committee, appointed for the purpose of making arrangements for the visit of the British Association, met on Monday. The Mayor, Alderman Elmsley, in opening the proceedings, said that some of the most eminent men of science in Europe and America had announced their intention of being present. Many of the principal manufacturers of Leeds had most generously consented to open their works for inspection by members of the Association. Arrangements had also been made for excursions to places of interest, historical or otherwise. He had no doubt that the inhabitants of Leeds would show all the hospitality and enthusiasm that was required. In the course of the proceedings it was stated that it was the original intention to have a guarantee fund of not less than £500, but that fund now amounted to not less than £6540. A report of the Executive Committee recommended that a call of 50 per cent. should be made on the guarantors, but Mr. Benson Jowitt, in moving the adoption of the report, expressed his belief that eventually it would turn out that the call had been more than sufficient to meet the demands which had been made upon it. The Vicar of Leeds, Dr. Talbot, having seconded the adoption of the report, it was carried, and the proceedings terminated.

THE National Association for the Promotion of Technical and Secondary Education has issued its third annual report. It speaks of the past year as the most eventful one of its existence, so far as the actual realization of the objects of the Association are concerned. The report will be of great interest to anyone who may wish to obtain a general view of the progress which is being made towards the establishment of a proper national system of technical and secondary education.

ATTEMPTS have been made in Parliament this week to secure that the money to be raised from the new tax on spirits shall be applied in Scotland to the establishment of a perfectly free system of elementary education. The Government declines to accept the proposal, which has, therefore, for the present been rejected. On Tuesday evening Mr. Goschen said the matter had been spoken of as a small one, but he thought the decision whether or not the standards above the compulsory standards as well as the compulsory standards themselves should be freed was by no means a very small question. The argument had been put forward that the Government would be justified in freeing parents from the duty (which hon. members now entirely discarded) of educating or contributing to the education of their children. They had relieved parents from that duty where the State had enacted compulsion, but the Government were not prepared to sanction the principle that beyond the compulsory standards education must necessarily be free. Mr. Mundella strongly supported the scheme. He pointed out that the compulsory standard varied in different districts from the third to the sixth. The compulsory standard had been fixed as a minimum, but the Chancellor of the Exchequer would tend to stereotype it, and in many places make it the maximum. Children were passing out of school at an earlier age year by year. In other countries the standard was not one of class, but of age. In Scotland children were passing the fifth standard as early as 10 or 11 years old. The payment of fees had been a great hindrance to the attendance of children at schools. That was why they were dealing with the question now. No doubt the child's wages were a great temptation, but the fee might just make the difference to a poor parent in deciding whether to keep his child at school or not. The present system was a great hardship on precocious children who passed the fifth standard at an early age.

THE Board of Agriculture announce that they have received information reporting the presence of the Hessian fly in the counties of Lincoln, Suffolk, and Herts slightly, and badly near Errol, in Perthshire. Owing to the twisted condition of much of the corn, it is more than usually difficult to detect the presence of the insect. Information is being prepared, and will at once be circulated by the Board.

THE returns presented to the Middlesex County Council by the various inspectors under the muzzling order show that during the quarter ending June last five dogs were seized with rabies in the county, as against seven in the previous quarter. But for the number of cases of rabies the Board of Agriculture would have been asked to withdraw the order. During the same period 526 dogs were seized, 87 of which were claimed and the remainder slaughtered. These figures compare with 1039, 108, and 946 respectively for the March quarter. The total number of dogs seized in the year was 3250, of which 488 were claimed and 2634 slaughtered. In the same period there were 49 cases of rabies, as against 22 in the previous year.

THE trustees of the South African Museum, in their Report for the year ended December 31, 1889, say that in the course of this period valuable assistance was rendered in the palæontological section by Prof. H. G. Seeley, F.R.S., who, during his brief visit to the colony, examined the South African fossils in the Museum, and determined and labelled a considerable number of them. The trustees were glad to learn that Prof. Seeley discovered in the Museum series an apparently new genus, and they had much pleasure in intrusting to his care some of the most interesting specimens for further investigation in England.

WE learn from the *Bulletin* of the Torrey Botanical Club that, through the cordial co-operation of the officers of the New York State Fish Commission, and the great personal interest of its President, Mr. Eugene Blackford, the Brooklyn Institute has been enabled to open a sea-side laboratory for teaching and research in zoology and botany, under the direction of Dr. Bashford Dean. The laboratory is located at Cold Spring Harbour, Long Island, 32 miles from New York, reached by the Long Island Railway. The session opened on July 7, and was to extend over eight weeks; the fee is 24 dollars. The location is described as a capital one, and an extensive corps of lecturers on special subjects has been secured, those on the botanical side being Dr. W. G. Farlow, Dr. N. L. Britton, and Prof. Byron D. Halsted.

THE death is announced of Dr. Alexander von Bunge, the veteran Professor of Botany at the University of Dorpat, at the age of 87. Dr. von Bunge was engaged, in the year 1830, in a scientific expedition in China, and subsequently in Khorassan and Afghanistan. His speciality of recent years was the flora of Russia and of Northern Asia. He was a foreign member of the Linnean Society of London.

SHOCKS of earthquake have lately been felt in different parts of Austria-Hungary. On July 23 two violent though short shocks took place in the Muehl district, in Upper Austria, and on July 25 a violent shock occurred in the valley of the Tscherna, in Moravia. A telegram received at Budapest from Mehadja on July 25 announced that two violent shocks of earthquake had been felt at the Hercules Baths, near that place, at half-past 11 on the previous night. The direction of the disturbance was from east to west.

THE Paris Museum of Natural History received recently from M. J. Bretonnière an interesting sample of limestone (from the suburbs of the town of Constantine in Algeria) in which there are a number of excavations, due apparently to *Helicidæ*. M. Stanislas Meunier thinks that land-snails are enabled to penetrate the rock through the agency of the siliceous particles which were shown by Hancock in 1848 to be the instruments used for similar work by some marine mollusks.

IN his recent thesis on the influence of the sea-shore on leaves M. Pierre Lesage shows by conclusive evidence that a marine, habitat leads to a thickening of the leaves. The palissade-cells are more numerous and larger than in the leaves of the same plants grown inland. Apparently the sea-salt is the cause of this alteration, as plants cultivated in artificially salted soil yield thicker leaves. The observations of M. Lesage bear on some ninety species of plants which are in their natural state found near the sea (in Brittany) as well as inland.

AN excellent paper on the Peabody Museum of American Archæology and Ethnology in Cambridge, U.S., by Frederick W. Putnam, has been reprinted from the Proceedings of the American Antiquarian Society, October 23, 1889. Mr. Putnam, dealing with the problems suggested by the collections of the Museum, thinks that the following are the elements to be taken into consideration in any endeavour to trace the present North American tribes and nations back to their origin. First, small oval-headed Palæolithic man. Second, the long-headed Eskimo. Third, the long-headed people south of the Eskimo. Fourth, the short-headed race of the south-west. Fifth, the Carib element of the south-east. All these elements, Mr. Putnam

holds, must be studied with their differences in physical characteristics, in arts, and in languages. "From a commingling of all," he says, "with greater or less predominance of one over the other, uniting here and subdividing there, through many thousand years, there has finally resulted an American people having many characteristics in common, notwithstanding their great diversity in physical characteristics, in arts, in customs, and in languages. To this heterogeneous people the name Indian was given, in misconception, nearly four hundred years ago, and now stands as a stumbling-block in the way of anthropological research; for under the name resemblances are looked for and found, while differences of as great importance in the investigation are counted as mere variations from the type."

THE Royal Society of Victoria has issued the second part of the first volume of its Transactions. Baron von Mueller begins this collection of papers with important "records of observations on Sir William Macgregor's highland plants from New Guinea." Mr. Arthur Dendy writes on the anatomy of an Australian land planarian; Prof. W. Baldwin Spencer on the anatomy of *Amphiptyches urna* (Grube and Wagner). A paper on the preparation of alkyl-sulphine, selenine, and phosphonium salts is by Prof. Orme Masson. Mr. A. W. Howitt, in a well-arranged and instructive paper, deals with the organization of Australian tribes. The following are among Mr. Howitt's conclusions:—(1) The group is the sole unit. The individual is subordinate in the more primitive form of society, but becomes more and more predominant in the advancing social stages. Thus group marriage becomes at length completely subordinate to individual marriage, or even practically extinct and forgotten where descent has been changed from the female to the male line. (2) An Australian tribe is not a number of individuals associated together by reason of relationship and propinquity merely. It is an organized society governed by strict customary laws, which are administered by the elder men, who in very many, if not in all, tribes exercise their inherited authority after secret consultation. (3) There are probably in all tribes men who are recognized as the headmen of class divisions, totems, or of local divisions, and to whom more or less of obedience is freely given. There are more than traces of the inheritance by sons (own or tribal) of the authority of these headmen, and there is thus more than a mere foreshadowing of a chieftainship of the tribe in a hereditary form. (4) Relationship is of group to group, and the individual takes the relationship of his group, and shares with it the collective and individual rights and liabilities. The general result arrived at is that the Australian savages have a social organization which has been developed from a state when two groups of people were living together with almost all things in common, and when within the group there was a regulated sexual promiscuity. The existence of two exogamous intermarrying groups seems to Mr. Howitt to almost require the previous existence of an undivided commune from the segmentation of which they arose.

AT the meeting of the Royal Society of Tasmania on May 20, Mr. Morton drew attention to a recent dredging trip in the harbour. The result of the dredging trip was of important interest, as the forms obtained resembled the marine fauna of Port Jackson. Among the specimens dredged were a large number of mussels, and each contained a small crab, which on examination appeared to belong to the genus Fabia. It was rather curious to learn from some of the old residents that many years back, when mussels were numerous as at present, in the majority of cases every mussel contained a crab similar to those exhibited, and that the oysters, while mussels were in large quantities, were few. Some time afterwards the mussel became nearly extinct, while the oyster multiplied. Whether that was due to this parasitical crab or not he was unable to say, but the fact was singular that while the crab was now noticeable in the mussel the oyster was increasing in numbers. Whether history would repeat itself it would be difficult to say, but it would be interesting to observe the result.

THE trustees of the State Museum of Natural History, New York, have issued their forty-first Annual Report. It is accompanied by the reports of the director, the State botanist, the State entomologist, and the State geologist. The directors call attention especially to the important and beautiful collection of minerals and gems bought for the Museum from Mr. George F. Kunz. They describe this collection as "one of the most perfect to be found in any American museum."

IN the seventh volume of the "Bulletin of the U.S. Fish Commission," lately issued, Dr. W. R. Hamilton has an interesting note on the croaking or grunting noise made by the "Perch" (*Haploidonotus grunniens*). This fish is furnished with a masticatory apparatus in the gullet, and the lower division of this has its upper surface flat and triangular in outline, and studded all over with spheroidal "teeth," if they may be called genuine teeth. The upper division is composed of two parts united by a ligament; their lower surfaces are also supplied with similar teeth. The divisions of this apparatus have powerful muscles attached to them by which they can be pressed together and moved laterally on each other. By this process the fish masticates the crustaceans on which it feeds. When this action takes place, the croaking is produced by the teeth coming in contact and gliding over each other. About twenty years ago, being interested in this subject, Dr. Hamilton procured from an Ohio River fisherman a perch weighing 18½ pounds, which he declared was the largest perch he had ever caught. Dr. Hamilton divided the head on one side, and thus exposed its masticatory apparatus; and while he moved its grinders as he supposed the fish had done during life when crushing a crawfish, an exact imitation of the croaking sound was produced.

THE Committee of the Felsted School Natural History Society, in issuing their eighth annual report, are able to congratulate the Society on a large increase of members during the past year. The members seem to give a good deal of attention to scientific study, but the Committee "continue to lament the very serious diminution of the old collecting spirit once so rife in the school, and to hope for its return." They attribute this defect to "compulsory games."

MESSRS. DEAN AND SON announce for publication "Berge's Complete Natural History of the Animal, Vegetable, and Mineral Kingdoms." It will be edited by R. F. Crawfurd, and illustrated with about 400 coloured plates and woodcuts.

PART 22 of Cassell's valuable "New Popular Educator" has been issued. The number is accompanied by a map of Africa, and there are, as usual, many illustrations.

THE new number of the Journal of the Royal Agricultural Society of England (third series, vol. i. part 2) begins with an article, by Mr. D. Pidgeon, on the development of agricultural machinery. This is followed by articles on the agricultural lessons of "the eighties," by Prof. Wrightson; the Report of the Royal Commission on Horse-breeding, by Lord Ribblesdale; tuberculosis in animals, and its relation to consumption in man, by Mr. W. Duguid; fifty years of hop-farming, by Mr. Charles Whitehead; the best means of increasing the home-production of beef, by Mr. G. Murray; and the herbage of pastures, by Dr. W. Fream.

THE Meteorological Office of Calcutta has just issued Part II. of "Cyclone Memoirs," containing a full description of a very violent cyclonic storm which passed through Bengal from August

21 to 28, 1888, written by Mr. A. Pedler. The text is accompanied by eighteen plates, giving the general meteorological conditions, and showing the track of the storm-centre day by day. Mr. Pedler states that this storm fully bears out the condensation theory of the formation of cyclones. It was formed over an area where comparatively low pressure had for some time been persistent, and there is abundant evidence of heavy rain falling over the district in which the storm was developed, and to the south of it. Several points of interest are referred to in the discussion, viz. the irregular cyclonic circulation of light winds near the centre of the storm, with a violent circulation of the clouds above these light winds, and these conditions appeared to shift their position, like an eddy; secondly, the sudden change from light winds to winds of hurricane force, extending chiefly in the southerly direction. Also the entire absence of a calm centre, and the fact that the lowest barometric pressure was recorded from ten to fourteen hours after the storm centre (as judged by the winds) had passed. The storm was remarkable for the slight barometric depression which accompanied it, considering the excessive force of the winds.

DR. R. J. SÜRING, of the Meteorological Office, Berlin, has submitted to the Friedrich-Wilhelms Universität, on the occasion of his taking his diploma, a useful paper on "the vertical decrease of temperature with height in mountainous districts, and its dependence upon the amount of cloud." In most works upon this subject, the special effect of cloud upon temperature has been limited to very moderate heights; in this paper the author has carefully investigated the observations at mountain stations up to about 4100 feet. The results arrived at are:—(1) In the morning, when the weather is clear, there is a constant tendency to an inversion of temperature. In summer this tendency extends to some 1650 feet, and in winter considerably higher. This condition recurs in the evening in a smaller degree. (2) If the sky is overcast, neither a daily nor yearly period of the vertical gradients is strongly marked. (3) A departure from the law of direct proportional decrease of temperature with height occurs chiefly during the morning hours of clear days—the change of temperature then takes place more slowly in the lower strata of air than in the upper—and on cloudy days, during the warm season, when, in the lower strata, the vertical decrease of temperature appears to be accelerated.

THE Allahabad *Pioneer* reports the result of a recent expedition to investigate the upper course of the Irawadi, the source of which, as is well known, is one of the still unsolved problems of geography. It has long been known from native report that two rivers, the Mali Kha and the Meh Kha, the former from the north, the latter from the east, unite a little below lat. 26° to form the Irawadi. The sources of the Mali Kha are known to be in the mountains to the east of the Brahmakund, which form the south-eastern water-parting of the Lohit Brahmaputra; but the Meh Kha, which is stated to be the larger stream, and which Colonel Walker supposes to be identical with the Lu River of Tibet, has never before been seen by any European. The junction of these two rivers has now for the first time been reached by an expeditionary party ascending from Bhamo. On May 27, Captain Barwick, of the Indian marine, accompanied by Mr. Shaw, the Deputy Commissioner of Bhamo, and Major Fenton, of the Intelligence Department, left Bhamo in the *Pathfinder*, a paddle-steamer of about 35 tons, with a view to reaching the point of confluence. From Bhamo as far as Maingna the stream is well known. Above Maingna the river runs between mountains from 1200 to 2000 feet high, and a succession of rapids has to be passed through, which by dint of hard struggling and after many attempts the *Pathfinder* successfully ascended, not, however, without several hairbreadth escapes from foundering, the whirlpools simply taking charge of the vessel. After six days' steaming, the party reached the confluence of the streams, distant about 150 miles from Bhamo. Here the river was found to be 500 yards wide, one branch, the Mali Kha, trending to the north-eastward, the other, the Nmaika (Meh Kha of the map), to the eastward. Up the former the explorers proceeded some six miles, and then came upon a series of rapids. It was decided not to go further, as the small quantity of fuel remaining was reserved for steaming up the other branch. A halt of a day was made, and the position fixed in lat. 25° 56′ N., and long. 97° 38′ E. Returning to the confluence, Captain Barwick proceeded three miles up the Nmaika, when a rapid prevented further progress. The Kachins are said to have been very friendly, though they had never seen or been in communication with Europeans before.

THE recent expedition to the Bellenden Ker Range (says the *Colonies and India*) has added a long and interesting list of new specimens of Australian flora to Queensland. Since the publication of the official report the Queensland Government Botanist (Mr. F. M. Bailey) has discovered ten more new plants, making a total of forty-one species entirely new to botanical science, and the collection is not yet exhausted. There are also several specimens of mosses and lichens, which so far have remained untouched, Mr. Bailey having had no time up to the present to devote to their examination. The total number of new species will probably extend to fifty—a result far exceeding that of any previous Australian botanical expedition. In the 1889 report of the proceedings of the Linnean Society of New South Wales there is an account of four new specimens to be added to the list of those discovered by the Bellenden Ker expedition. One of these belongs to the genus *Coccincillidæ*, and has been named *Chilocorus Baileyi*, after the Queensland botanist. A large and remarkable dark blue earthworm, over seven inches long, has been named *Perichæta terræ-reginæ*—the latter a rather pedantically inflated version of *Queenslandia*. The worm was found by Mr. Meston on the top of the Herberton Range, at 2700 feet, and given to the Brisbane Museum. Two Bellenden Ker lizards of a genus new to Australian herpetology have been named by Mr. C. W. de Vis, Curator of the Queensland Museum. They belong to the order *Geckonidæ*, and are called respectively *Tropidophorus Queenslandiæ* and *Perochirus Mestoni*, the latter after the discoverer.

AN experimental study of the transpiration of plants has been recently made (we learn from *Humboldt*), by Herr Eberdt, of Marburg. The general method was to periodically weigh an air-tight vessel containing the roots of a plant (chiefly *Asclepias incarnata*, *A. Cornuti*, or *Mercurialis perennis*) in water, while the organs of transpiration projected. Absorption was also measured by means of a graduated capillary tube. We may note the following points:—The absorption and emission-values did not generally differ much. Increase of transpiration by sunlight occurred though the latter had parted with its heat-rays by passage through an alum solution; but when, after action of diffuse daylight, the dark heat-rays of sunlight (passed through a solution of iodine in carbon-sulphide) were thrown on the plants, transpiration was also increased. Direct sunlight causes more emission than absorption (shown by a relaxed appearance of the plant); and on passage into duller light, the emission falls off more quickly than the absorption, and the plant freshens. In plants with strong cuticle or few stomata, there was but little increase of transpiration from drying the air in a bell-jar over the plant by means of a dry air-current. The stomata of *Trianea bogotensis*, being watched through a microscope while light- and heat-rays were thrown on the plant from above, they were seen to open more slowly if the heat-rays were cut off; but with heat-rays alone they remained closed. If opened in light, they remained open when the heat-rays acted alone, and closed when these too

were stopped. A sooty metallic plate at 30° to 25° held 3 to 5 seconds over the leaf opened the stomata, while dark heat-rays of sunlight failed to do so. The stomata opened also on passing a stream of warm, nearly saturated, air over the leaves. A shaking of plants acts not by way of shock, but by changing the atmosphere about the leaves, and therefore like wind. Strong shaking stimulates transpiration; while weak vibration has no perceptible effect. The effect of wind was studied by directing air-currents of measured strength on the plants. The action of the weaker currents proved proportionally greater than that of stronger. The transpiration is greater if the leaves are free to be moved than if they are fixed.

THE additions to the Zoological Society's Gardens during the past week include two Ravens (*Corvus corax*), British, presented by Mr. Walter Chamberlain, F.Z.S.; two Wheatears (*Saxicola œnanthe*), two Whinchats (*Pratincola rubetra*), two Great Tits (*Parus major*), British, presented by Mr. J. Young, F.Z.S.; a Cuckoo (*Cuculus canorus*), British, presented by Mr. Valentine Marks; a Black Tortoise (*Testudo carbonaria*) from Jamaica, presented by Master Morris Blake; a Dwarf Chameleon (*Chamæleon pumilis*) from South Africa, presented by Mr. H. Tholen; a Brazilian Hangnest (*Icterus jamaicai*), two Bluish Finches (*Spermophila cærulescens*), a Tropical Seed-Finch (*Oryzoborus torridus*), a Thick-billed Seed-Finch (*Oryzoborus crassirostris*) from Brazil, a Black-faced Kangaroo (*Macropus melanops* ♂) from South Australia, deposited; a Thar (*Capra jemlaica* ♀), two Mule Deer (*Cariacus macrotis* ♀ ♀), five Cuming's Octodons (*Octodon cumingi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on July 31 = 18h. 37m. 53s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4447	—	Bluish-green.	18 49 27	+32 53
(2) D.M. + 31° 3199 ...	5	Yellowish-red.	18 7 46	+31 23
(3) 70 Ophiuchi	4	Yellow.	17 59 54	+ 2 32
(4) o Herculis	4	Bluish-white.	18 3 18	+28 45
(5) 219 Schj.	8	Red.	18 43 57	− 8 1
(6) V Coronæ	Var.	Yellowish-red.	15 45 35	+39 54

Remarks.

(1) The well-known Ring Nebula in Lyra, which has been described in great detail by various observers. The spectrum consists of bright lines, but the line near λ 500 is the only conspicuous one. When the image of the nebula is sharply focussed on the slit, the chief line is seen as two bright dots connected by a faint line, indicating that nebulous matter fills the interior of the ring. (This is also confirmed by the telescopic appearance.) The line F and the one near λ 495 are exceedingly faint, but they are undoubtedly present. In my own observations, with a 10-inch refractor, I have also glimpsed a less refrangible line, but have not been able to determine its position with any degree of accuracy. Further investigation of this line should be made with as large an aperture as possible. It is not far from *b*.

(2) D'Arrest and Dunér agree in describing the spectrum of this star as one of Group II. with well-developed bands. The bands at the red end are the strongest, indicating that the star is well advanced in condensation. The bands in the red are the last to disappear in passing to stars like α Tauri, and hence this conclusion. As in similar stars, the line absorptions at this stage afford an interesting study. We do not know yet, for instance, the stage at which the hydrogen lines first appear, although we now certainly know that they are present in α Orionis. The same also applies to D and *b*.

(3) The integrated spectra of the components of this double star present an appearance similar to that of a well-developed star of the solar type. No attempt has apparently yet been made to separate the two spectra. This should be done, if possible, and the usual more detailed observations as to whether the temperature is increasing or decreasing should be made.

(4) A star of Group IV. (Gothard).

(5) According to the observations of Dunér, this star has a fine spectrum of Group VI., the principal bands being very wide and dark. In addition to these, the secondary bands 4 and 5 (λ 589 and 576 respectively) were easily seen, and band 2 (λ 621) was also feebly visible. What is most required in this group of stars is a very detailed examination with the largest possible apertures. If such be undertaken, particular attention should be given to the presence or absence of line absorptions.

(6) This variable is chiefly of interest because its spectrum is one of Group VI. We have as yet no knowledge, as we have in the case of variables of Group II., of the variations of spectrum which accompany the increase of light at maximum. The range of variation in V Coronæ is very considerable—7·5 to 12 in a period of about 357 days; and it is not unlikely that well-marked changes may take place in the spectrum. Dunér states that the carbon band near λ 564 is weaker than that near λ 517, and that the secondary bands are not visible; but he gives no indication of the magnitude of the star at the time of his observation. Prof. Lockyer's investigations appear to indicate that the dark carbon bands should be proportionately less strongly marked at maximum than at minimum. There will be a maximum about August 5.

A. FOWLER.

DISTRIBUTION OF THE PERIHELIA OF COMETS.—In 1880, Dr. Henry Muirhead directed attention to the arrangements which the perihelia of comets exhibit in relation to the sun's line of flight, and pointed out that, taking the twenty-two comets given in the "Encyclopædia Britannica" along with thirteen others whose elements were given in NATURE up to the date of his communication, and arranging them according to their heliocentric longitudes, the perihelia were seen to be crowded into the quadrants which the sun's line of flight bisects, as compared with those taking place in the quadrants flanking the said line (Proceedings of the Philosophical Society of Glasgow, vol. xiii.). By examining the succeeding volumes of NATURE, Dr. Muirhead has obtained the heliocentric longitudes of the perihelia of forty-one more comets, and in a communication to the Philosophical Society of Glasgow, on February 5, 1890, he showed that they also exhibit the same tendency to cluster near heliocentric longitudes 263° and 83°—that is, the longitude of the "apex" and "quit" of the sun's way adopted by him.

It will be remembered that Mr. H. S. Monck, in a letter to the *Observatory*, in December 1888, remarked that, in examining catalogues of comets, he found 177 comets with perihelia north of the ecliptic, against 115 with southern perihelia. With respect to this circumstance, Mr. Monck wrote:—"Our observing stations are chiefly situated in northern latitudes. Comets are rarely visible when very remote from their perihelia; therefore, comets which pass their perihelia north of the ecliptic are more likely to be detected and observed than comets which pass their perihelia to the south of it. . . . As the point towards which the sun is moving lies to the north of the ecliptic, it might be expected that more comets would, on the whole, come to us from the north than from the south. But a comet coming from the north will usually have its aphelion north and its perihelion south. The fact that three-fifths of the comets have their perihelia to the north and their aphelia to the south thus becomes more significant, and I can hardly regard it as *wholly* the result of the position of our observing stations."

Later, however (August 1889), Dr. Holetschek drew attention to a pamphlet "Ueber die Richtungen der grossen Axen der Cometenbahnen," in which he shows that "the tendency of comet perihelia or aphelia to accumulate rather in small latitudes, and about the longitudes 90° and 270° than in other places, can be explained by purely terrestrial considerations, and, consequently, this accumulation offers no proof of the motion of the solar system or of the ultra-solar origin of comets." In fact, it appears that the distribution in latitude of the perihelia of comets is nearly uniform, and has not a marked maximum in the latitudes of the sun's line of flight, although, as Dr. Muirhead indicates, a clustering of aphelia and perihelia occurs near the heliocentric longitude of the line.

THE ROCKS OF THE MOON.—M. Landerer, in continuation of his memoir last year on the polarizing angle of the lunar surface, has just communicated to the Paris Academy the results of some determinations of the angle of polarization of igneous rocks. He finds that specimens from different localities give practically identical results, the probable errors never being greater than ± 5′. The polarizing angle increases from 30° 51′ for ophite, through syenite, basalt (31° 43′), serpentine, trachyte, granite (32° 20′), diorite, diabase, andesite (32° 50′), to obsidian (33° 46′). Vitrophyre, a black rock from the Rhodope chain, which contains large crystals of sanidine, magnetite, and hornblende, in a fluidal, non-perlitic matrix, has a polarizing angle of 33° 18′, which approximates very closely to that of the lunar surface. Without presuming too much on this result, the author regards it as at any rate an additional proof of the similarity, and therefore common origin, of our earth and its satellite. The fact that the polarizing angle of ice is more than 37°, is another objection to M. Hirn's hypothesis of lunar glaciation.

BROOKS'S COMET (*a* 1890).—Dr. Bidschof gives the following ephemeris in *Astronomische Nachrichten*, No. 2979:—

Ephemeris for Berlin Midnight.

1890.	R.A. h. m. s.	Decl.	Log r.	Log Δ.	Brightness.
Aug. 1	13 11 1	+45 37·9	0·3121	0·3714	1·38
5	13 7 39	43 57·9	0·3160	0·3849	1·27
9	13 5 4	42 24·2	0·3200	0·3978	1·18
13	13 3 9	40 56·5	0·3242	0·4100	1·09
17	13 1 45	39 34·5	0·3285	0·4215	1·02
21	13 0 47	38 17·7	0·3330	0·4323	0·95
25	13 0 12	37 5·8	0·3376	0·4423	0·89
29	12 59 58	35 58·6	0·3422	0·4517	0·83
Sept. 2	12 59 54	34 56·1	0·3470	0·4605	0·78

The brightness on March 21 has been taken as unity.

BRORSEN'S COMET.—Mr. E. Barnard, of Lick Observatory, notes, in the above number of *Astronomische Nachrichten*, that he has made many searches for this comet from December of last year to the end of April, but with only a negative result. He notes that during the search he has found several unrecorded nebulæ.

TWO NEW COMETS (*b* and *c* 1890).—M. Coggia, at Marseilles, has discovered a pretty bright comet having the following positions (*Astronomische Nachrichten*, 2980).

Marseilles Mean Time. h. m.	R.A. h. m. s.	Decl. ° ′ ″
July 18 ... 10 31·0	8 48 51·0	+44 42 48
19 ... 9 38·8	8 55 58	44 2 48

Mr. Denning discovered a faint comet at Bristol on July 23; its position at 13 hours Greenwich mean time being R.A. 15h. 12m., and Decl. +78°. It was moving towards the east (*Edinburgh Circular*, No. 8).

A NEW ASTEROID (294).—M. Charlois, of Nice Observatory, discovered an asteroid of the twelfth magnitude on the 15th inst.

THE SCIENTIFIC PRINCIPLES INVOLVED IN MAKING BIG GUNS.

II.

PART II.—THE STRAINS IN THE GUN.

(29) SO far we have dealt only with the stresses in the metal, and we have determined these stresses in the manner given by Rankine in his "Applied Mechanics," § 273, p. 290, in which the only assumption made is that the metal of each cylinder is homogeneous. But when the gun-maker wishes to set up a given pressure of shrinkage between two cylinders, he has to determine, by calculation or experiment, the slight amount by which, when cold, the external radius of one cylinder must exceed the internal radius of the next cylinder which is shrunk on it; the outer cylinder being expanded by heat and slipped on, in order that the given initial pressure may be set up on the cooling of the outer cylinder; and this, too, when other cylinders are shrunk on afterwards.

We must therefore determine the strains and deformations set up in a given cylinder due to given applied pressures, and thus we require the equations giving the strains due to given applied stresses when the coefficients of elasticity of the metal are known.

[1] Continued from p. 309.

(30) Now, it is proved in Thomson and Tait's "Natural Philosophy," §§ 682, 683, for a substance of which k is the elasticity of volume or bulk-modulus, and n is the elasticity of figure or rigidity, that when the stress is a simple longitudinal tension P, the principal strains in the substance are an extension $P\left(\frac{1}{3n} + \frac{1}{9k}\right)$ in the direction of the tension, and a compression $P\left(\frac{1}{6n} - \frac{1}{9k}\right)$ in all directions perpendicular to the tension.

We use the words *tension* and *pressure*, as before, to denote *stresses* measured in terms of pull or thrust per unit area, with our practical units, measured in tons per square inch; while the words *extension* and *compression* are used (in accordance with the terminology of Maxwell, Everett, and Unwin) to mean the *strains*, measured by the ratio of linear elongation or contraction to the original length.

Thus, the *tension* or *pressure* being the *stress*, the *extension* or *compression* is the corresponding *strain*; and Hooke's law of elasticity (*ut tensio sic vis*), translated into a formula, gives $\frac{\text{stress}}{\text{strain}} = \frac{\text{tension}}{\text{extension}} = \frac{\text{pressure}}{\text{compression}}$ = the modulus of elasticity.

(31) Then, by superposition, if e, f, g are the extensions produced in three rectangular directions by tensions P, Q, R in these directions—

$$e = \left(\frac{1}{3n} + \frac{1}{9k}\right)P - \left(\frac{1}{6n} - \frac{1}{9k}\right)(Q + R), \quad . \quad . \quad (31)$$

with two similar expressions for f and g; or, in Thomson and Tait's notation, § 694—

$$Me = P - \sigma(Q + R), \quad . \quad . \quad . \quad . \quad . \quad . \quad (32)$$
$$Mf = Q - \sigma(R + P), \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$
$$Mg = R - \sigma(P + Q), \quad . \quad . \quad . \quad . \quad . \quad . \quad (34)$$

where

$$\frac{1}{M} = \frac{1}{3n} + \frac{1}{9k}, \text{ or } M = \frac{9nk}{3k + n},$$

so that M is Young's modulus of elasticity, the modulus which is directly observable when a test-piece of the substance (steel) is placed in a testing-machine, and the ratio $M = P/e$ is observed of P, the tension, to e, the extension, no lateral tension being applied, or

$$Q = 0, R = 0;$$

also,

$$\sigma = \frac{3k - 2n}{6k + 2n},$$

called Poisson's ratio, is the ratio of the lateral compression to the linear extension of the substance when the stress is a simple tension.

(32) Again, by independent investigation, as in § 692, or by solution of the preceding equations (32, 33, 34), we find—

$$P = \left(k + \frac{4}{3}n\right)e + \left(k - \frac{2}{3}n\right)(f + g), \quad . \quad . \quad (35)$$
$$Q = \left(k + \frac{4}{3}n\right)f + \left(k - \frac{2}{3}n\right)(g + e), \quad . \quad . \quad (36)$$
$$R = \left(k + \frac{4}{3}n\right)g + \left(k - \frac{2}{3}n\right)(e + f); \quad . \quad . \quad (37)$$

or, in Lamé's notation ("Théorie de l'Élasticité," § 19)—

$$P = \lambda\theta + 2\mu e,$$
$$Q = \lambda\theta + 2\mu f,$$
$$R = \lambda\theta + 2\mu g,$$

with

$$\theta = a + b + c,$$

the cubical expansion; and

$$\lambda = k - \frac{2}{3}n, \ \mu = n.$$

The above equations show that when the strain is given as a simple uniform longitudinal extension e, the stresses consist of a uniform longitudinal tension, $(k + \frac{4}{3}n)e = (\lambda + 2\mu)e$, in the direc-

tion of the strain, and of uniform lateral tension, $(k - \frac{2}{3}n)e = \lambda e$, in every direction perpendicular to the strain.

(33) These equations, and the previous equations, which show that, when the stress is a simple uniform longitudinal tension P, the strains consist of a uniform extension P/M in the direction of the tension, and of uniform lateral compression σP/M perpendicular to the tension, are so fundamental in the theory of the elasticity of isotropic bodies, that we are almost tempted to make a digression here on their proof, in the manner given in Thomson and Tait's "Natural Philosophy," §§ 682, 683, and 692.

It is necessary to describe and compare the notations carefully, for subsequent purposes, as the variety of notation in the subject of elasticity is very confusing.

(34) Applying these principles to the gun, we take the three principal directions of stress and strain, as (i.) circumferentially to the gun, (ii.) radially, (iii.) longitudinally; and now, estimating *tensions* and *extensions* as positive, we have—

$$P = t = ar^{-2} - b,$$
$$Q = -p = -ar^{-2} - b;$$

while the value of R is still indeterminate.

For the determination of the strains, we denote by u the *increase* of radius, r, of a circumferential fibre; and then $2\pi u$ being the elongation of the fibre of original length $2\pi r$, the circumferential extension

$$e = 2\pi u/2\pi r = u/r;$$

while the radial extension $f = du/dr$; the longitudinal extension g being as yet undetermined.

(35) Expressing the strains e and f in terms of the longitudinal tension R,

$$\begin{aligned} Me = Mu/r &= P - \sigma(Q + R) \\ &= ar^{-2} - b + \sigma(ar^{-2} + b) - \sigma R \\ &= (1 + \sigma)ar^{-2} - (1 - \sigma)b - \sigma R; \end{aligned}$$

or

$$Mu = (1 + \sigma)ar^{-1} - (1 - \sigma)br - \sigma Rr; \quad . \quad . \quad . \quad (38)$$

so that, differentiating with respect to r,

$$\begin{aligned} Mf &= Mdu/dr \\ &= -(1 + \sigma)ar^{-2} - (1 - \sigma)b - \sigma d(Rr)/dr \\ &= Q - \sigma P - \sigma d(Rr)/dr. \end{aligned}$$

But with

$$Mf = Q - \sigma(R + P),$$

Barlow, Lamé, and Hart's expressions for the stresses are verified, provided that

$$d(Rr)/dr = R;$$

or

$$dR/dr = 0, \qquad R = \text{constant}.$$

(36) On the other hand, expressing the strains e and f in terms of the longitudinal strain or extension g, since

$$\begin{aligned} R &= \sigma(P + Q) + Mg, \\ Me = Mu/r &= P - \sigma(Q + R) \\ &= (1 - \sigma^2)P - \sigma(1 + \sigma)Q - \sigma Mg \\ &= (1 - \sigma^2)(P - \sigma'Q) - \sigma Mg, \end{aligned}$$

putting

$$\sigma' = \frac{\sigma}{1 - \sigma};$$

so that

$$Mu = (1 - \sigma^2)\{(1 + \sigma')ar^{-1} - (1 - \sigma')br\} - \sigma Mgr; \ . \ (38^*)$$

and differentiating with respect to r,

$$\begin{aligned} Mf &= Mdu/dr \\ &= (1 - \sigma^2)(Q - \sigma'P) - \sigma Md(gr)/dr, \end{aligned}$$

agreeing again in giving

$$Mf = Q - \sigma(R + P,$$

provided that

$$d(gr)/dr = g;$$

or

$$dg/dr = 0, \qquad g = \text{constant}.$$

We have proved, then, that either the longitudinal tension R or the longitudinal extension g of the gun must be uniform, for the values of the stresses given by the formulas of Barlow, Lamé, Hunt, and Rankine, to be strictly accurate; we shall follow the ordinary practice in assuming that R is uniform, but the work will be almost precisely the same if we assume that g is uniform (Prof. P. G. Tait, "On the Accurate Measurement of High Pressures," Proc. R.S. Edinburgh, 1879–80).

(37) Now, let us determine, for the simplest case of the tube A and the jacket B, the requisite *shrinkage* for producing a given initial pressure $\varpi_o = p_i$ at their common surface; the shrinkage, denoted by S, being defined as the excess of the outside diameter $2\rho_o$ of the tube A over the inside diameter $2r_i$ of the jacket B, when both are finished cold in the lathe; so that

$$\tfrac{1}{2}S = \rho_o - r_i.$$

The jacket B is now expanded by heat till its inside diameter is greater than $2\rho_o$, and then slipped over the tube A; on cooling, the jacket B shrinks and grips the tube A with the requisite pressure, $p_i = \varpi_o$.

Taking the practical rule that the expansion of steel is one-ten-thousandth for every 15° F., the jacket must be raised in temperature something over 150,000 $S/2r_i$ degrees Fahr.

Denoting by u and v the outward displacement of any circumferential fibre of the jacket or tube, of radius r in the jacket and ρ in the tube; then, since the tube and jacket fit closely at their common surface,

$$\rho_o + v_o = r_i + u_i,$$

or

$$u_i - v_o = \rho_o - r_i = \tfrac{1}{2}S.$$

(38) Supposing the tube and jacket to be both of steel of the same quality, so that M, the modulus of elasticity, is the same for both; and assuming that R is uniform, then in the jacket B, from (38),

$$Mu_i = (t_i + \sigma p_i)r_i - \sigma Rr_i,$$

and in the tube A,

$$Mv_o = (-\tau_o + \sigma\varpi_o)\rho_o - \sigma R\rho_o;$$

and now, since $p_i = \varpi_o$, and we may put $r_i = \rho_o$, subtraction gives—

$$M(u_i - v_o) = (t_i + \tau_o)r_i,$$

or

$$S = (t_i + \tau_o)2r_i/M; \ . \ . \ . \ . \ . \ . \ (39)$$

and t_i and τ_o having been determined either from the formulas (6) to (16), or graphically from Fig. 3, from the given value of $p_i = \varpi_o$, the requisite value is determined of the shrinkage S, or of $S/2r_i = (t_i + \tau_o)/M$, which is the shrinkage, estimated as a fraction of the diameter.

This formula shows us that the shrinkage S is the elongation or contraction which would be produced in a bar of steel, one square inch in section, and equal in length to the diameter $2r_i$, by a pull or thrust of $t_i + \tau_o$ tons.

If we had taken g as uniform, we should find in a similar manner—

$$S = (1 - \sigma^2)(t_i + \tau_o)2r_i/M. \ . \ . \ . \ . \ (40)$$

With steel, $\sigma = \frac{1}{4}$ about, so that $\sigma' = \frac{1}{3}$; and the values of the shrinkage calculated on the two assumptions of uniform R and uniform g, would be in the ratio of 1 to $1 - \sigma^2$, or as 16 to 15; thus differing by about 6 per cent., a difference which is practically insensible.

(39) In the numerical example we have given of the initial stresses of the tube and jacket, $t_i = 5$, $\tau_o = 5$; so that $S/2r_i = 10/M$.

For gun steel M = 12,600 about (Unwin, "Testing of Materials of Construction," p. 249); and supposing the tube and jacket to represent a 3-inch field gun, $2r_i = 6$; and then

$$S = 1/210 = 0{\cdot}00476,$$

4·76 thousands of an inch.

(40) In heavy guns, one or more hoops are shrunk on over the jacket; for instance, in the 110-ton gun, three such series are superposed. Diagrams in section of modern guns will be found in recent numbers of the *Engineer* and of *Engineering*.

The addition of each hoop that is shrunk on modifies the initial stresses previously existing. The annexed diagram (Fig. 7), taken from the American "Notes on the Construction of Ordnance," Nos. 31, 33, 35, by Lieutenant Rogers Birnie, shows the shrinkage (enlarged 50 times) of the different parts, and the intermediate and final arrangements when a jacket, B, an inner hoop, C, and an outer hoop, D, are successively shrunk on the tube A of the American 8-inch gun, shown in longitudinal section in Fig. 8.

But knowing the initial stresses in the gun, as determined in the manner already explained in Part I., we can determine the requisite shrinkage at each common surface, for any number of layers, by a formula as simple as that just found for the tube A and jacket B, if only we assume that M, the modulus of elasticity, is the same throughout.

(41) Denote, as before, by p_m, the radial pressure at the radius, r_m, of the common surface of the mth and m + 1th hoops, as reckoned from the interior; and by t'_m, t_m the circumferential tensions at the exterior radius, r_m, of the mth hoop, and at the interior radius, r_m, of the m + 1th hoop.

Denote also by u'_m, u_m, the outward radial displacement from the unstrained position of the outer surface of the mth hoop, and of the inner surface of the m + 1th hoop.

Then, with uniform R, from (38),

$$Mu_m = (t_m + \sigma p_m)r_m - \sigma R r_m,$$

$$Mu'_m = (t'_m + \sigma p_m)r_m - \sigma R r_m;$$

so that

$$M(u_m - u'_m) = (t_m - t'_m)r_m.$$

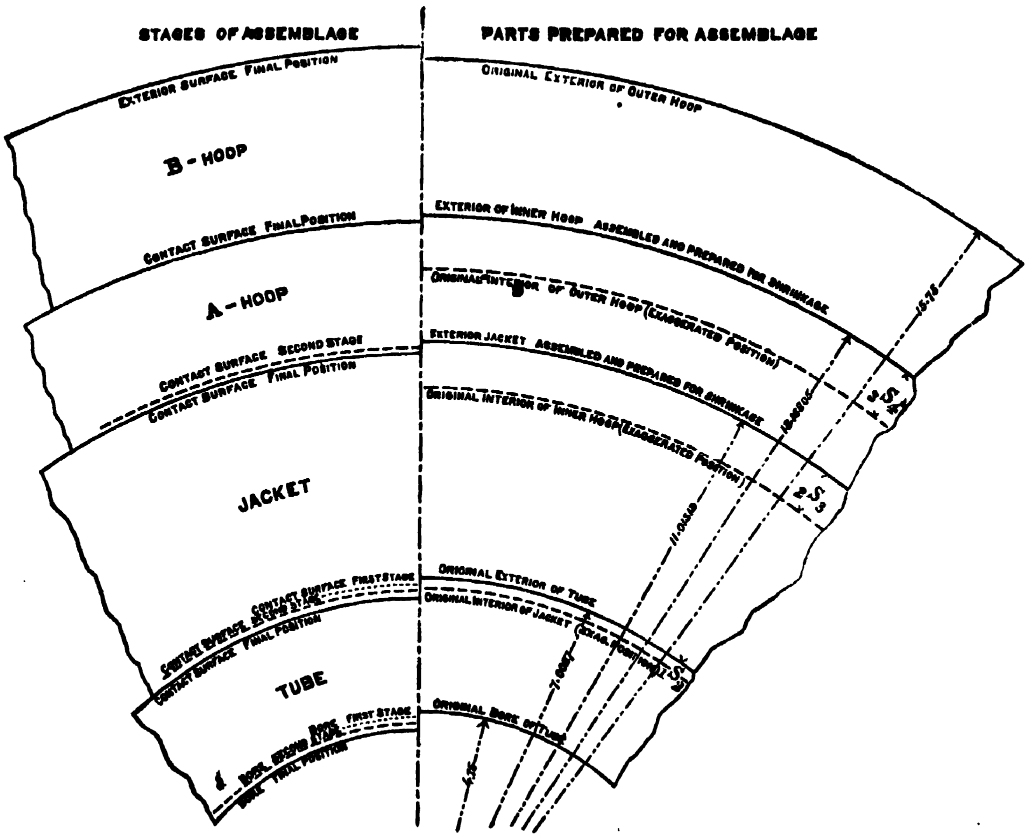

FIG. 7.

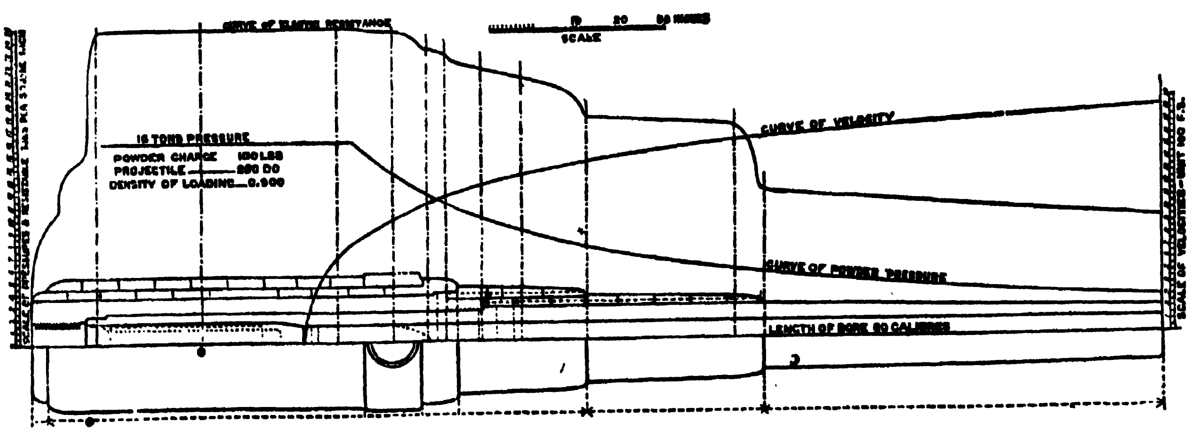

FIG. 8.

Now, using the notation ${}_mS_{m+1}$ to denote the shrinkage when unstrained between the mth and m + 1th hoops,

$$\begin{aligned} {}_mS_{m+1} &= 2(u_m - u'_m) \\ &= (t_m - t'_m)2r_m/M, \quad . \quad . \quad . \quad . \quad (41) \end{aligned}$$

the same as for a single tube, A, and jacket, B; and showing that the shrinkage, ${}_mS_{m+1}$, is the elongation or contraction which would be produced in a bar of steel, of modulus of elasticity M, one square inch in section, and of length equal to the diameter $2r_m$, by a pull or thrust of $t_m - t'_m$ tons. On the assumption of uniform g, we should find—

$${}_mS_{m+1} = (1 - \sigma^2)(t_m - t'_m)2r_m/M, \quad . \quad . \quad . \quad (42)$$

practically the same as for uniform R.

(42) The stress formulas in the mth hoop give—

$$2a_m = (p_m + t'_m)r_m^2 = (p_{m-1} + t_{m-1})r_{m-1}^2.$$

$$2b_m = (p_m - t'_m = p_{m-1} - t_{m-1};$$

so that

$$t_m - t'_m = (t_m - t_{m-1}) - (p_m - p_{m-1}).$$

These values of t_m and t'_m are the initial stresses or circumferential tensions; and as the powder pressure p_0 increases them by equal amounts, their difference is unaltered; so that $t_m - t'_m$ is the same for the initial stresses or the firing stresses; and we may calculate the shrinkage, S, by the above formula from the values of the firing stresses, or of the initial stresses; the former being chosen, as given more directly when the maximum allowable tensions, represented by t_m, are given.

(43) As a numerical illustration, let us calculate the shrinkages in the American 8-inch gun, taking the previous results of § 22, and M = 12,600 (tons per square inch) for all the coils.

Then the final contraction of the bore

$$ {}_0S_1 = t_0 \times 2r_0 \div M = 19{\cdot}9 \times 10 \div 12{,}600 = 0{\cdot}016, $$

or 16 thousandths of an inch; and similarly,

$$ {}_1S_2 = 12{\cdot}7 \times 14 \div 12{,}600 = 0{\cdot}014; $$
$$ {}_2S_3 = 10{\cdot}7 \times 22 \div 12{,}600 = 0{\cdot}019; $$
$$ {}_3S_4 = 3{\cdot}6 \times 26 \div M = 0{\cdot}007; $$
$$ {}_4S_5 = 8{\cdot}1 \times 32 \div M = 0{\cdot}021, $$

the elongation of the external diameter of the last coil.

Lieutenant Rogers Birnie, following Clavarino ("Note on the Construction of Ordnance," No. 6), calls the *extension* or *compression* the *relative elongation* or *relative contraction;* so that the above values of ${}_0S_1$, ${}_1S_2$, ${}_2S_3$, ${}_3S_4$, ${}_4S_5$, must be divided by 10, 14, 22, 26, 32, to obtain his values of the relative elongation or contraction; and then, by § 37, 150 thousand times the relative elongation or contraction is the number of degrees Fahrenheit a jacket or coil must be raised in temperature to be expanded sufficiently so as to slip over the inner cylinders.

A. G. GREENHILL.

(*To be continued.*)

THE TOKIO TECHNICAL SCHOOL.

THE *Japan Weekly Mail* in a recent article describes the Tokio Technological School, situated at Asakusa, a suburb of that city. The inclosure in which the school buildings stand formerly belonged to the Shôgun's Government, and was used for the storage of rice. Several of its storehouses, which were ranged round a creek or blind canal leading off the river, still remain, and are utilized by the institution. A frame building of two stories, the chief modern portion, faces the roadway and runs at right angles to the creek. Here are the offices, showrooms, and lecture-rooms; the workshops are to be found between this building and the river. There are two great departments in the school, the Technological and the Mechanical. Of these the former is the more varied and interesting. To it are attached a dyeing shop, porcelain and glass furnaces, and technological laboratories; to the mechanical department are attached a drawing office, a pattern shop, and a foundry.

The history of the school begins with its foundation in 1882, for the purpose of training foremen and managers for manufactories, and instructors for industrial schools. It was intended that the course of instruction should include all branches of industrial education concerned with arts and manufactures. The course was to extend over three and a half years, of which the first year should be devoted to general preparatory instruction and the others to special training in some particular branch. Next year certain alterations were made, making the course one of four years, and raising the standard. In August of that year the first batch of students, numbering sixty in all, were admitted. The school was shortly afterwards brought into connection with the Imperial University, and placed under the control of that institution—a step which led to a complete change in its curriculum. The preparatory course was abolished, and a short complete course, extending over two years, was instituted. Again, in 1888, a new Imperial decree severed its connection with the University, and placed it under the direct control of the Education Department. The school set itself anew to remodel its course of instruction, abolishing the short general course and resuming the course of three years; and elective courses were established with the view of making the school more popular and generally useful to mechanics and craftsmen. The laboratories and workshops are each provided with responsible superintendents, foremen, and assistants. The general direction is in the hands of a Committee, consisting of the manager of the school, two officials of the Education Department, and two officials of the Department of Agriculture and Commerce. Candidates for entrance to the regular courses must be not under seventeen nor over twenty-five years of age, and unless they have passed satisfactorily through a normal or middle school, must undergo an examination in Japanese, arithmetic, algebra and geometry, physics and chemistry, and English translation. Students sent up by local governments need not undergo this examination. The elective courses have been instituted for the benefit of artisans and mechanics, who, having no general scientific training, are anxious to study some part of the regular course. These candidates receive this privilege only when the convenience of the school admits of it, and are allowed to study for two years, taking one or more of the subjects immediately connected with their special crafts. An elective student must be at least seventeen years of age, and must have followed, for more than one year, some trade having special relation to the subjects of instruction which he has chosen. The fee paid by these students is about 3*s.* monthly.

In the mechanical engineering section-boilers, steam-engines, force-pumps—these last happen now to be in great demand in Japan as an improvement on the clumsy well-bucket—and sawing-machines are manufactured. The shop is also prepared to execute orders for steam and hot-water heating apparatus, and has already fitted up the new Engineering College in the University grounds with a complete set of hot-water pipes and fittings. All the casting and founding required by the College are carried out at the Asakusa School. An improved pattern of perforating machine, now in use at the Imperial Printing Office, is also turned out. It is claimed for this pattern that it possesses a superiority over the one in common use in Europe for perforating stamps and other paper. Experiments are likewise in process on printing-presses, with the view of perfecting a machine for native use. The dyeing department is chiefly concerned with practical instruction in the best methods of fixing colours, rather than in any more original researches. Of late years the importation into Japan of aniline dyes has increased to such an extent that the total annual value of these imports now exceeds £35,000. Unfortunately, although these colours are very attractive to buyers, their proper use is still little understood. Silk, cotton, and other fabrics which have been coloured by native dyers do not wash well, and half the imported dye-stuffs run to waste. It is one of the chief aims of the instructors in this department to teach artisans how to fix these colours. Just now the school dye-shop is busying itself with this particular branch, and also with a series of experiments on the dyeing of mountain silk. This silk, which is soft in texture and durable in wear, refuses the ordinary dye, a circumstance attributable to the presence in it of a large amount of calcium carbonate. The pottery and glass department is associated with the name of Dr. Wagner, who has for a long series of years enjoyed the confidence of the Japanese Government. Dr. Wagner is admitted to be the best authority on all matters connected with Japanese technology, and has directed his particular attention to the fabrication of a ware known in Japan as *asahi-yaki*, and elsewhere as Dr. Wagner's faience. Unlike the Satsuma, which is also faience, but of a much harder kind, this ware receives its decoration when in its unglazed state, which is a manifest advantage. It is made chiefly from a clay found in the Enya district of the Tochigi prefecture, with slight admixture of clays from other localities. The colour of the faience when baked varies from white, having a warm brown tinge, to lightish pink. Much of the *asahi-yaki* is exported to Germany and to the United States, and a certain amount to France, but little or none finds its way to Great Britain. Artists are at work on the spot decorating the plates and other articles preparatory to the receiving of the glaze. The object which Dr. Wagner and his colleagues have in view is technological and not artistic, and consists in perfecting native potters in the manipulation of the material.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for June 1890 contains:—On the embryology of a scorpion (*Euscorpius italicus*), by Malcolm Laurie (Plates xiii.-xviii.). The develop-

ment of this scorpion, of which very elaborate details are given, would appear not to agree closely with any other Arachnid type as yet described; the development of the central and lateral eyes entirely confirms the descriptions of Lankester and Bourne, as well as those of Parker, but Patten's conclusions are shown to be without foundation. The mode of formation of the ventral nervous system is exceptional among Invertebrates, resembling rather that of Chordata.—On the morphology of the compound eyes of Arthropods, by S. Watase (Plate xix.). Reprinted, with a short introduction by the editor, from a recent number of the "Studies from the Biological Laboratory, Johns Hopkins University."—On the structure of a species of earthworm belonging to the genus Diachæta, by Frank Beddard (Plate xx.). This new species, *D. windlei*, is from the Bermudas.—On *Hekaterobranchus shrubsoli*, a new genus and species of the family Spionidæ, by Florence Buchanan (Plates xxi. and xxii.). This worm was found at Sheppey in soft mud, usually covered by an inch or so of brackish water; in addition to the figures of the anatomical details there are coloured portraits of this Annelid.—An attempt to classify earthworms, by Dr. W. B. Benham. Some idea may be formed of the progress made within the last twenty years in our knowledge of this group when we state that the author enumerates and gives analyses of nine families of Lumbricomorpha, containing thirty-two genera and over 200 species. The author wishes the following correction made:—In Fig. 39, which illustrates the anatomy of Lumbricus, the œsophageal pouch (CP) is placed in somite xi.; followed by a pair of calciferous glands in the same somite and a second pair in somite xii. The pouch (CP) should be in somite x.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—"Contributions to the Molecular Theory of Induced Magnetism." By J. A. Ewing, F.R.S., Professor of Engineering in University College, Dundee.

After referring to the discussion by Maxwell of Weber's theory, which ascribes the magnetization of iron and other magnetic metals to the turning towards one direction of molecules which are already permanent magnets, and to suggestions by Profs. Wiedemann and Hughes, and lately by Mr. A. E. Kennelly (the *Electrician*, June 6 and 13, 1890), the writer describes experiments which he has made bearing directly on the molecular theory. The experiments have been made by grouping near to one another a large number of small pivotted magnets each free to turn about a fixed centre, and studying the configuration which the group assumes and the manner in which it yields when an external magnetic force is imposed. The results do not support the idea that the molecular magnets form closed chains in unmagnetized iron. They lead, however, to the important conclusion that no arbitrary conditions of directional constraint need be postulated to make the behaviour of the molecular magnets agree with what is known about magnetic quality.

In the writer's view the molecular magnets are perfectly free to turn in response to external magnetic forces, except in so far as they are constrained by the magnetic forces which they mutually exert on one another. This theory is briefly discussed in the paper in relation to the form of the magnetization curve, to the character of cyclical processes, and to the known effects of temperature, vibration, stress and so forth, and the following conclusions are stated:—

(1) That in considering the magnetization of iron and other magnetic metals to be caused by the turning of permanent molecular magnets, we may look simply to the magnetic forces which the molecular magnets exert on one another as the cause of their directional stability. There is no need to suppose the existence of any quasi-elastic directing force or of any quasi-frictional resistance to rotation.

(2) That the intermolecular magnetic forces are sufficient to account for all the general characteristics of the process of magnetization, including the variations of susceptibility which occur as the magnetizing force is increased.

(3) That the intermolecular magnetic forces are equally competent to account for the known facts of retentiveness and coercive force, and the characteristics of cyclic magnetic processes.

(4) That magnetic hysteresis and the dissipation of energy which hysteresis involves are due to molecular instability resulting from intermolecular magnetic actions, and are not due to anything in the nature of frictional resistance to the rotation of the molecular magnets.

(5) That this theory is wide enough to admit explanation of the differences in magnetic quality which are shown by different substances, or by the same substance in different states.

(6) That it accounts in a general way for the known effects of vibration, of temperature and of stress, upon magnetic quality.

(7) That, in particular, it accounts for the known fact that there is hysteresis in the relation of magnetism to stress.

(8) That it further explains why there is, in magnetic metals, hysteresis in physical quality generally with respect to stress, apart from the existence of magnetization.

(9) That, in consequence, any not very small cycle of stress occurring in a magnetic metal involves dissipation of energy.

Anthropological Institute, June 24.—E. W. Brabrook, Vice-President, in the chair.—Mr. J. E. Price exhibited parts of a skeleton found at West Thurrock, Essex.—Mr. H. H. Risley read a paper on the study of ethnology in India. This paper states the results of certain inquiries into the customs and measurements of the features, stature, &c., of some of the chief tribes and castes in India, conducted during the last five years under the authority of the Government of Bengal. Owing to the influence of the caste system, which forbids intermarriage between members of different castes, India offers a peculiarly favourable field for anthropological researches. The measurements disclose the existence of two extreme types—the Aryan and Dravidian. The Aryan type—as represented by the Brahmans, the Rajputs, and the Sikhs—is tall and fair, with a finely cut nose, and features on the whole superior to those of the average European. The Dravidians, as seen in the Kol tribes, who recently revolted against the oppression of their Hindu landlords, are short and very black, with a broad flat nose, closely approaching in its dimensions to that of the Negro. The proportions of the nose are regarded by European anthropologists—by Prof. Flower, F.R.S., of the British Museum, and Prof. Topinard, of Paris—as the best test of race distinctions. The Indian statistics bear out this opinion. They show that in Bengal caste is so closely connected with race that the social standing of a caste is in inverse ratio to the average width of the noses of its members. The lower the caste the broader and more Negro-like is its nose; and conversely, in ascending the social scale, we meet with continually finer noses, till in the higher castes European proportions are reached. The proportions of the head are of interest in connection with the theory propounded by Herr Karl Penka, of Vienna, and favoured by Prof. Sayce, that the Aryans were a dolichocephalic (long-headed) race who came originally from Scandinavia. The long-headed type is very numerous in the Punjab and North-West Provinces at the present day, and its distribution is such as to give considerable support to Herr Penka's opinions. The inquiry has also brought to light the existence in Bengal of totems such as are found among the North American Indians. Large tribes, like the Kols, are subdivided into two or three hundred groups, each of which is called after an animal, a tree, or a plant; and the rule is that a member of a particular animal group, such as the snakes, the tortoises, the eels, or the mangooses, may not marry within that group. Thus a snake man may not marry a snake woman, but must select his bride from among the frogs, the tortoises, the mango-trees, or a host of groups which include the whole fauna and flora of the district. The paper attempts to account for this custom, which the late Mr. J. F. McLennan called *exogamy*, by connecting it with the theory of natural selection. Among other interesting facts the Bengal inquiry shows that the practice of infant marriage, and the custom forbidding widows to marry a second time, are greatly on the increase, and are being adopted by the lower castes as marks of social distinction. It is feared that the spread of infant marriage will have a weakening effect on the race, and will multiply and aggravate those special diseases of women which Lady Dufferin's Fund was instituted to deal with. The increase in the number of widows is in itself a great evil. It lowers the position of women in India, and tends to lower the standard of social morality.

PARIS.

Academy of Sciences, July 24.—M. Hermite in the chair.—M. Boussinesq presented the second and last volume of his "Course of Infinitesimal Analysis," and commented upon the

application therein given of the integral calculus to physics and mechanics.—New researches on the relative stability of salts in the solid and dissolved state: aniline salts, by M. Berthelot. The author compares the heat of formation and the properties of the more stable aniline salts, such as the sulphate, nitrate, and chloride with the unstable ones, *e.g.* the acetate and benzoate. The observations furnish a new confirmation of thermo-chemical theories.—Heat of formation of certain amides, by MM. Berthelot and Fogh. The amides investigated are acetamide, propionamide, benzamide, and succinimide; and the experiments show that the heat of formation of anilides, *e.g.* acetanilide and benzanilide, is greater than that of the corresponding amides.—The share of the end-plates of motor nerves in the expenditure of the energy which produces contraction; influence exercised on the heating of a muscle by the number and nature of the changes of state which the end-plates excite in the contractile bundle, by M. A. Chauveau.—Discovery of a comet by M. Coggia at Marseilles Observatory. (See Our Astronomical Column.)—On the means of recognizing the *Cysticerci* (bladder worms) of *Tænia saginata*, which cause "measles" in the calf and ox, in spite of the rapid disappearance of the *Cysticerci* on exposure to the air, by M. A. Laboulbène.—On the sensibility of plants when regarded as ordinary reagents, by M. Georges Ville. The author has extended to peas and wheat his observations in 1867 on yeast as a test for phosphoric acid, and finds that their varying growth is an indication of extreme delicacy for very minute amounts.—On the production by electric discharges of images reproducing the principal characteristics of solar activity, by M. Ch. V. Zenger.—On the combination of observations, by M. R. Lipschitz. This is an extension of Gauss's application of the calculus of probabilities to errors of observation.—The diagrammometer: an additional apparatus for the study of curves, by Colonel Kozloff.—On the physical property of the surface of contact of two liquids under the influence of mutual affinity, by M. G. Van der Mensbrugghe.—On internal crystalline reflection, by M. Bernard Brunhes.—On the double elliptic refraction of quartz, by M. F. Beaulard.—On a magnetic anomaly observed in the neighbourhood of Paris, by M. Th. Moureaux. A discussion of the earliest results of a detailed magnetic survey of France now being made indicates that regions of local disturbance exist in the Paris basin.—Researches on the double phosphates of titanium, tin, and copper, by M. L. Ouvrard.—Researches on the optical dispersion of organic compounds: the ethers, by MM. Ph. Barbier and L. Roux.—Upon certain hydrates of the haloid esters, by M. Villard. The author finds that the iodide and fluoride of methyl form hydrates like the chloride and bromide. Experiments on the haloid compounds of ethyl show that the chloride and fluoride yield similar hydrates. The fluorides were gases prepared by M. Moissan's process, and yielded colourless crystalline hydrates.—On oxygluconic acid, by M. L. Boutroux. The author has obtained by the oxidation of either glucose or gluconic acid by bacterial action an acid, to which he gives the name oxygluconic, having the formula of glucoronic acid, $C_{12}H_{10}O_{14}$, but differing from the latter in being lævorotatory, very soluble in alcohol, and not yielding crystals on evaporation. The new acid appears to be identical with one recently obtained by M. Emile Fischer by the replacement of the acid radical of saccharic acid with an aldehyde group, using the action of sodium amalgam on its lactone.—On the examination of the impurities contained in alcohol, by M. Ed. Mohler.—On a new process for the determination of mineral matters in sugar by means of benzoic acid, by M. E. Boyer.—On the mineral springs of Cransac (Aveyron), by M. Ad. Carnot.—On the combinations of hæmoglobin with oxygen, by M. Christian Bohr.—Possibility of injections into the human trachea as a means of introducing medicines, by M. R. Botey.—Claim of priority in the discovery of craniectomy, by M. Guéniot.—On the mechanism of respiration in *Ampullaria*, by MM. Paul Fischer and E. L. Bouvier.—On the repair of the shell in *Anodon*, by M. Moynier de Villepoix. Numerous experiments on the growth in water with varying amounts of chalk in solution of the shell after artificial injuries indicate that it is a product of secretion of the mantle, that it is at first a purely organic formation, and that the lime for its consolidation is obtained from the surrounding medium.—On the secretion of silk in *Bombyx mori* (common silkworm), by M. Raphael Dubois. —The gangrene of the potato stem, a bacterial disease, by MM. Prillieux and G. Delacroix.—On the angle of polarization of igneous rocks and the chief lunar deductions therefrom, by M. J. J. Landerer. (See Our Astronomical Column.)

BERLIN.

Physiological Society, June 18.—Prof. du Bois-Reymond, President, in the chair.—Dr. Blumenau gave an account of his researches on the development of the corpus callosum, carried out chiefly upon the brains of embryonic pigs, from which he concluded that the grey matter on the upper and lower sides of this structure grows by a fusion with the neighbouring bundles of arched fibres.—Prof. H. Virchow spoke on the gill-slits of the sturgeon, which he had examined with a view to finding a transitional form between the gills of Selachians and the osseous fishes. His anatomical and embryological investigations showed that with reference to its gills the sturgeon does not occupy that intermediate position which has been assigned to it by zoologists.—Prof. Gad described an experimental confirmation by Dr. Zagari of Donders's statement, denied by Knoll, that the inhaling of carbonic acid at the end of an expiration materially increases the depth of the ensuing inspiration. He had further found that this reflex effect is not observed after section of the vagi, and is not affected by section of the recurrent laryngeals. It did not take place when a glass tube was pushed down the trachea and one bronchus, so as to protect these portions of the air-passages from the action of the gas; but it reappeared on withdrawing the tube until its end rested at the bifurcation of the bronchi. From this it follows that the reflex inspiration is set up by the action of the gas on the mucous membrane of the bronchi. The effect was observed when the carbonic acid gas was diluted with 50 per cent. of air, but not upon further dilution. Marshall Hall's theory of respiration receives no confirmation from the above experiments. The concentrated CO_2 which makes its exit into the lungs themselves is probably inactive owing to its inevitable dilution by the residual air.

CONTENTS.

THURSDAY, AUGUST 7, 1890.

THE HISTORY OF BOTANY.

History of Botany (1530–1860.) By Julius von Sachs. Authorized Translation by H. E. F. Garnsey, M.A. Revised by Prof. I. Bayley Balfour, F.R.S. (Oxford: Clarendon Press, 1890.)

AFTER fifteen years' interval, this admirable book has made its appearance in English. The translation does justice to the original, and to say this is very high praise, for the "History of Botany" is perhaps the most generally interesting, and the most finished in style, of all Prof. Sachs's works.

There have been scarcely any alterations in this edition, which still represents the state of the author's mind in 1875. To quote his words, in his preface to the present translation:—

"I came to the conclusion that my book itself may be regarded as a historical fact, and that the kindly and indulgent reader may even be glad to know what one, who has lived wholly in the science, and taken an interest in everything in it, old and new, thought from fifteen to eighteen years ago of the then reigning theories, representing as he did the view of the majority of his fellow botanists."

The paragraph which follows must, we think, in fairness be quoted, though this is done with some regret:—

"However, these remarks relate only to two famous writers on the subjects with which this history is concerned. If the work had been brought to a close with the year 1850 instead of 1860, I should hardly have found it necessary to give them so prominent a position in it. Their names are Charles Darwin and Karl Nägeli. I would desire that whoever reads what I have written on Charles Darwin in the present work should consider that it contains a large infusion of youthful enthusiasm still remaining from the year 1859, when the 'Origin of Species' delivered us from the unlucky dogma of constancy. Darwin's later writings have not inspired me with the like feeling. So it has been with regard to Nägeli. He, like Hugo von Mohl, was one of the first among German botanists who introduced into the study that strict method of thought which had long prevailed in physics, chemistry, and astronomy; but the researches of the last ten or twelve years have unfortunately shown that Nägeli's method has been applied to facts which, as facts, were inaccurately observed. Darwin collected innumerable facts from the literature in support of an idea; Nägeli applied his strict logic to observations which were in part untrustworthy. The services which each of these men rendered to the science are still acknowledged; but my estimate of their importance for its advance would differ materially at the present moment from that contained in my 'History of Botany.' At the same time, I rejoice in being able to say that I may sometimes have overrated the merits of distinguished men, but have never knowingly underestimated them."

We are sorry that these words have been written. The position of Darwin in biology needs no defence, even when the assailant is Prof. Sachs. With regard to Nägeli, the case is different; but, although recent investigation has re-opened some of the questions which he appeared to have decided, we feel that here also the critic's first thoughts were best, and that the estimate of 1875 is, in the main, more just as well as more generous than that of 1889.

A very brief sketch of the contents of the work, which will already be familiar to so many botanical readers, must suffice. The first of the three books into which the whole work is divided is occupied with the history of morphology and classification, from 1530 to 1860. The early efforts at classification by the German and Dutch botanists of the sixteenth century are first discussed, and it is shown that they were already guided by the perception of natural affinity—an idea which, as the author says, "is not the discovery of any single botanist, but is a product, and to some extent an incidental product, of the practice of describing plants." But for a time these necessarily feeble attempts at a natural arrangement had to give way to artificial systems based on *a priori* principles of classification. Of this tendency Cesalpino is the first great representative, and the author shows how great was the influence of this remarkable man on the succeeding period of systematic botany. It was Cesalpino who first founded a classification mainly on the organs of fructification.

The period inaugurated by Cesalpino culminates in Linnæus.

"Linnæus," says Prof. Sachs, "in whose works the profound impression which he had received from Cesalpino is everywhere to be traced, retained all that was important in his predecessor's views, but perceived at the same time what no one before him had perceived, that the method pursued by Cesalpino, Morison, Ray, Tournefort, and Bachmann, could never do justice to those natural affinities which it was their object to discover; and that in this way only an artificial though very serviceable arrangement could be attained, while the exhibition of natural affinities must be sought by other means" (p. 81).

The author does full justice to the unrivalled excellence of Linnæus as a descriptive botanist, and further points out that his fragment of a natural system was much the most truly natural proposed up to the middle of the eighteenth century. Linnæus's famous sentence, "It is not the characters which make the genus, but the genus which makes the characters," shows, indeed, a remarkable insight into the meaning of natural affinity.

The development of the natural system by the two Jussieus, Pyrame de Candolle, Robert Brown, and other illustrious systematists is next traced. In the concluding chapter of the first book there is a fine sketch of the splendid work of Hofmeister in establishing the relations between Cryptogams and Phanerogams, and of his position relative to the theory of descent. The author says (p. 202):—

"When Darwin's theory was given to the world eight years after Hofmeister's investigations, the relations of affinity between the great divisions of the vegetable kingdom were so well established and so patent, that the theory of descent had only to accept what genetic morphology had actually brought to view."

The subject of the second book is the history of vegetable anatomy. An admirable account is given of the work of the great founders of the anatomy of plants in the seventeenth century, Malpighi and Grew, who remained the leading authorities in this branch of science

for 130 years. In speaking of the period of barrenness which followed this brilliant beginning, the author is especially severe on our own country. "In England," he says (p. 246), "the new light was extinguished with Hooke and Grew, and has so remained, we may almost say, to the present day." We may hope that, if this passage had been written fifteen years later, Prof. Sachs would have found some reason to modify his judgment.

The following chapters deal with the revival of vegetable anatomy and histology in the present century. Due justice is done alike to the patient investigations of von Mohl and to the brilliant method of the erratic Schleiden, while, as will be gathered from what has been said above, the many-sided activity of Nägeli receives in the text fully adequate recognition.

The third book is on the history of vegetable physiology, and this is of special interest from the fact that the author is himself the leading physiological botanist of our time. The first chapter is concerned with the history of the sexual theory. The chief credit for the discovery of sexuality in plants is given to Camerarius of Tübingen, who in 1694 published the first experimental researches on the necessity of fertilization for the ripening of the seed; though in special cases, as those of the fig and the date-palm, the fact of sexuality had been known even to Theophrastus and Pliny. The author justly points out that Linnæus, though his system called general attention to the existence of male and female organs in the flower, had little or nothing to do with the discovery of their functions.

The following passage discusses the relation of Kaspar Friedrich Wolff to the old theory of "evolution," according to which all the parts of the mature organism pre-exist in little in the embryo.

"Wolff conceived of the act of fertilization as simply another form of nutrition. Relying on the observation, which is only partly true, that starved plants are the first to bloom, he regards the formation of flowers generally as the expression of feeble nutrition (*vegetatio languescens*). On the other hand, the formation of fruit in the flower was due to the fact that the pistil found more perfect nourishment in the pollen. In this, Wolff was going back to an idea which had received some support from Aristotle, and is the most barren that can be imagined, for it appears to be utterly incapable of giving any explanation of the phenomena connected with sexuality, and especially of accounting for the results of hybridization. Wolff may have rejected the theory of evolution on such grounds as these, but he failed to perceive what it is which is essential and peculiar in the sexual act" (p. 405).

This passage appears of special importance, for theories akin to those of Wolff have reappeared even in our own day.

The investigations of Koelreuter on hybridization, and those of Sprengel on cross-fertilization, the full significance of which was first shown by Darwin 60 or 70 years later, mark the closing years of the eighteenth century. But, in spite of all that had been done, there were still some botanists who, on more or less feeble grounds, expressed doubts as to the sexuality even of the Phanerogams, and it was the work of Gärtner, towards the middle of the present century, which "once more confirmed the existence of sexuality in plants, and in such a manner that it could never again be disputed."

The concluding sections of this chapter give the remarkable history of the discovery of the details of fertilization in the flowering plants, and sketch the rise and progress of our knowledge of corresponding processes among the Cryptogams. These are subjects on which an immense amount of good work has been done in more recent years, and some future historian will have much to add to Prof. Sachs's brilliant summary.

The nutrition of plants forms the subject of the next chapter of the "History." The ideas of the ancients are first considered, and then the gradual rise of the modern doctrine of assimilation is traced from its first beginnings in the discoveries of Malpighi and Hales, of whom the former showed that the green leaves are the organs which prepare the food, while Hales proved that a large part of this food is taken up in a gaseous form. It would be useless to attempt to summarize this interesting story. Probably no piece of scientific history has ever been better told, and few, if any, are better worth the telling. Prof. Sachs is here, above all, on his own ground, and we are conscious that we are reading the words of a great master. It is scarcely necessary to add that here, also, more recent research has been extremely active, and modern investigations on such questions as the source of the nitrogen in plants, and the course of the ascending sap, will probably do much to modify the views expressed in this work.

The concluding chapter is on the movements of plants, and here, once more, the historian is treating of phenomena of which he is himself among the greatest investigators.

The translators and the Clarendon Press deserve the warmest thanks of English readers, whether botanical or not, for bringing before them a scientific history distinguished at once by its clearness, its fairness, and the author's unrivalled mastery of his subject.

D. H. S.

A TEXT-BOOK OF PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY.

Text-book of Physiological and Pathological Chemistry, in Twenty-one Lectures for Physicians and Students. By Dr. G. Bunge, Professor of Physiological Chemistry at Bâle. Translated from the second German edition by the late L. C. Wooldridge, M.D., and completed for the press by his Wife. (London: Kegan Paul, 1890.)

THE appearance of Bunge's text-book in its English dress reminds us keenly of the loss which physiology has sustained by the death of the translator. It is some consolation to be able to temper this regret with the satisfaction that so interesting and instructive a work was made available to English students by one so capable as the late Dr. Wooldridge. He wisely contented himself with translating the original without those annotations or additions which are often supplied, and which, while they may be of intrinsic merit, frequently destroy the individuality of the original. Criticism of Dr. Wooldridge's share in the English version thus resolves itself into asking how he has done his work as a translator, and the answer is: "Admirably." While

the original text is closely followed and accurately rendered, the result is, unlike some translations, such pleasant reading that the student will scarcely realize that it is a translation. But in justice to the author it must be said that this is also partly due to the simple style and language of the original, and to the lecture-form of its arrangement.

The aim of the author has been to deal with such portions of the subject as are "ripe for a connected account," omitting "all disconnected facts and mere descriptive matter" and all descriptions of analytical methods; to provide such references to the literature of the subject as shall more particularly suffice to put the student on the track of the remainder; and thus as a whole to tell the reader what is most certainly known, and to enable him to pursue further any points in which he is specially interested. In all this the author has been very successful, and particularly with respect to the references to original memoirs, which are quoted judiciously and comprehensively. The work is divided into twenty-one lectures. Of these the first propounds the author's views as to the "aims and prospects of modern physiological research," and consists of a somewhat remarkable protest against the modern tendency to regard cell-activity as the expression and outcome of chemical, physical, and mechanical processes. It is indeed a distinct return to the vitalistic views of the past, and urges the existence of some psychological factor of activity, based on the belief that "for the moment it is not apparent how any further progress of importance can be made with the help of chemistry, physics, and anatomy only;" and concludes by saying that "what these sciences fail to achieve will stand out more prominently, and thus the mechanical theories of the present will assuredly carry us eventually to the vitalism of the future." There are probably few physiologists who will agree with this view. Most will rather hold with Heidenhain (*Pflüger's Archiv*, xliii., Suppl.-Hft. p. 63) that, granted the existence of the psychological factor, still it must produce its recognizable effects by purely chemical, physical, and mechanical means, and accept those views of the "activity" of a cell which stand out so clearly in his masterly work on secretion.

The second and third lectures treat of the chemical elements which constitute living organisms, their circulation through the vegetable and animal kingdoms, the principle of the conservation of energy as applied to living things, and, finally, the correlation of plants and animals. The next three lectures deal with the organic food-stuffs and foods, their composition, importance, and function, in connection with nutrition. In these a clear and comprehensive account is given of the various endeavours which have been made to determine the molecular weight of proteids. The sections on the *rôle* of gelatin and cellulose, and of a vegetarian diet in general, are most instructive, and there is a very full statement of the physiology of the organic compounds of iron, leading up to the author's views as to the mode of action of iron-salts in the treatment of chlorosis. Lecture VII., on the inorganic food-stuffs, contains an interesting and valuable account of various salts, more particularly those of sodium and potassium, in their relationship to nutrition; and Lecture VIII. concludes this part of the subject by treating of subsidiary articles of diet, such as tea, coffee, alcohol, bouillon, &c. Digestion and the absorption of digestive products form the subject-matter of Lectures IX.-XII. In these the well-selected and copious references to the literature of the subject will be found to be by no means the least valuable part. Lecture XIII., on the chemistry of blood and lymph, will probably disappoint those who turn to it for an account of the clotting of blood. Perhaps Prof. Bunge thinks the subject not yet "ripe for a connected account," and this is, perhaps, to a large extent true. Still, he would have done well to treat it from a general point of view, rather than almost entirely with regard to the part played by the leucocytes: some account at least of the work of Hammarsten and the translator seems called for in connection with this part of the subject. The gases of the blood, and their relation to the processes of external and internal respiration, are dealt with in the next two lectures. These call for no special remark apart from saying that the fact that the oxidations of the body take place in the tissues might have been more decisively brought out. Existing views as to the condition of CO_2 in the blood are clearly stated. Lecture XVI. gives an admirable exposition of recent work and existing views as to the seat and mode of formation of the nitrogenous products of metabolism, followed, in natural sequence, by a chapter on the functions of the kidneys and chemistry of urine. Hepatic metabolism is the subject of Lecture XVIII. In this the questions which arise with regard to its glycogenic activity are scarcely so clearly put forward as might be expected. On the other hand, the older and current views on fat-formation are well explained in Lecture XX. The remaining lectures (XIX. and XXI.) deal with the source of muscular energy and diabetes respectively.

It is well for those English students who cannot read the original that this interesting and instructive work by Prof. Bunge has, in this well-turned version, been made accessible to them. We cannot conclude better than by hoping it may attain the recognition and approval in this country which it so fully deserves from every point of view, and which it appears to have already secured in the original, judging by the speedy issue of the second edition, of which the copy here reviewed is a translation.

THE ADVANCEMENT OF SCIENCE.

The Advancement of Science: Occasional Essays and Addresses. By E. Ray Lankester, M.A., LL.D., F.R.S. (London: Macmillan and Co., 1890.)

UNDER this title, Prof. Ray Lankester has republished a number of essays, which have appeared at intervals during the last eighteen years. All of them are of more or less permanent interest, and we are glad to have them presented to us in the convenient form of a well-printed octavo volume. While some of the essays are somewhat too technical for the general reader, the majority are of great and very general interest, well worthy of being read and thought over by all.

These essays are nine in number. The last treats of the history and scope of zoology, and is reprinted from the last edition of the "Encyclopædia Britannica"; it forms a most excellent treatise on the subject, and fairly though briefly sketches the history of zoology from the

seventeenth century to the present day. In the second essay the relations that should exist between the State and biology are considered, and there can be little doubt but that as a result of this address to the Biological Section of the British Association at Southport, followed by the fifth essay, which gives an outline of the scientific results of the International Fisheries Exhibition, held in London in the same year (1883), we are in great measure indebted for the valuable help given by our Government towards the establishment of the Laboratory at Plymouth belonging to the Marine Biological Association of the United Kingdom.

The third and sixth essays, on Pasteur and hydrophobia —or rabies, as we would prefer to call this formidable disease—and on centenarism, are full of interest, and while in the former the author has to content himself with a narration of the chief results of Pasteur's invaluable labours, in the latter we find an account of a subject which has been critically worked out by himself.

Three of the essays relate to the subject of Darwinism, and possibly will be found the most interesting in the volume. The first is on the subject of "Degeneration, a chapter in Darwinism," and was delivered as one of the evening lectures at the British Association meeting at Sheffield, in 1879. In it Prof. Lankester calls attention to the fact that degeneration, or the simplification of the general structure of an animal, may be due to the ancestors of that animal having taken to one of two habits of life, either the parasitic or the immobile. Other new habits of life appear also to be such as to lead to degeneration. Let us suppose, for example, a race of animals fitted and accustomed to catch their food, and having a variety of organs to help them in this chase; suppose such animals suddenly to acquire the power of feeding on the carbonic acid dissolved in the water around them, just as green plants have. This would lead to degeneration; for they would soon cease to hunt their food, and would bask in the sunlight, taking food in by the whole surface, as plants do by their leaves. Another possible cause of degeneration appears to be the indirect one of minute size. And so, as is well shown, this hypothesis of degeneration enables very numerous cases of animal structure to be accounted for. The second of this set, forming the seventh of the collected series, is on parthenogenesis, and in it we find the fascinating accounts given to us by the painstaking zeal of von Siebold of the habits and manners of the little wasps belonging to the genus Polistes—a story both wonderful and romantic. The third of these, the eighth of the whole set, treats of Haeckel's theory of heredity, in which the transmission of acquired characters by heredity is discussed, but this phase of belief Prof. Lankester will no longer insist upon, and he points out that Weismann's essays on this question should be carefully studied by naturalists.

The last essay to be alluded to is the fourth, on examinations. The author claims that but few have had a wider or a more continuous experience in examinations than he has had. On this somewhat vexed question he has a good deal that is to the point to say, showing that the use of examinations in schools and Universities is different from their use as a test of fitness for entrance into a profession, or a post in the Home or Indian Civil Service, or as a means of deciding a question of relative merit.

We feel sure that as each of these essays originated in a desire to promote the interests of science, so the author, in collecting the present series, will be found to have had the same aim in view.

OUR BOOK SHELF.

Agenda du Chimiste. Par MM. Salet, Girard, et Pabst. (Paris: Hachette and Co., 1890.)

IN this volume will be found a most complete and exhaustive compilation of facts and numerical tables of use to the chemist. The first edition was published in 1877 by M. Wurtz, and in subsequent editions the work has been thoroughly brought up to date. It is now published annually as a chemical year-book, the publication of each year containing a few special articles called for by the events of the past twelve months. This year the following are among the special articles contributed: "The Progress of the Industry of Colouring Matters," "Review of the Exhibition of 1889" as regards matters of chemical interest, and "Views of the International Chemical Congress concerning Nomenclature." The numerical data included in the book are most full, and ought to be of great service in the reduction of observations. The collection of them represents an immense amount of labour, and the accompanying descriptions of experimental methods are very clear and concise. A most useful portion of the work is that in which all the known physical constants of the elements and numerous compounds are given. Special care appears to have been taken in collecting the published thermo-chemical data, with the result that the chapter upon this subject is one of the most valuable in the book. The tables for use in quantitative analysis, and especially those referring to commercial methods, will doubtless be fully appreciated for the saving of time and arithmetical labour which their use will effect. It is, moreover, of no mean advantage that all formulæ are given according to the ordinary nomenclature, and not according to the old notation still retained by many French chemists. The volume is small and handy in spite of its five hundred pages, and cannot fail to be of service in the laboratory. A. E. T.

The Philosophy of Clothing. By W. Mattieu Williams. (London: Thomas Laurie, 1890.)

MR. WILLIAMS is a somewhat eccentric writer, and by most people some of the notions set forth in this little book will be regarded as "fads." He is generally able, however, to give a good reason for the opinions he advances, and much of his advice, although opposed to the rules of fashion, is sound and practicable. The subject is one which occupied the close attention of Count Rumford; and of his researches Mr. Williams, as he himself says, has made "free use."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Zoological Affinities of *Heliopora cerulea*, Bl.

THE remarkable blue coral, *Heliopora cerulea*, of Blainville, represents, I believe, one of those species that, in common with *Stylaster*, *Millepora*, and other allied genera, have been recently relegated to the Hydrozoic subdivision of the Cœlenterata. So far as I remember, however, and without having present access

to the most recent literature of this subject, *Heliopora* was thus transferred with reference to the structure of its corallum only, the living animal having been but imperfectly if at all observed.

In the course of my professional investigations of the fisheries of Torres Straits I have on several occasions obtained specimens of *Heliopora*, but had hitherto been unsuccessful in observing the living animal. Last year I obtained this coral on the Warrior Reef near New Guinea, but while apparently living when collected, and kept for days on board ship with the water continually changed, the zooids refused to make their appearance. Through the courtesy of Captain Dawson, R.N., and the officers of H.M.S. *Rambler*, I have this season journeyed north in that ship, and was afforded the opportunity of conducting a series of investigations in the neighbourhood of the Adolphus Islands, off Cape York, close to the scene of the recent *Quetta* wreck, and with relation to which the *Rambler* had been told off to make a careful survey.

At low spring-tide on the reef adjacent to the "Mid-Brother" rock, I came across a luxuriant growth of *Heliopora*, and was fortunate on this occasion to accurately determine the nature of the fabricators of this remarkable coral. The first living manifestations presented, and those visible only with the aid of a pocket lens, were the protrusion of a transparent body and two elongate tentacles from the numerous circular pores with which the corallum is studded. At first sight some near affinity of the animal to the bitentaculate Hydrozoon *Lar sabellarum* of Gosse was suspected. The movements of the zooids during extension and retraction were, however, more active than those which usually obtain among the Cœlenterata, and together with their general aspect and comportment suggested a nearer relation to the Annelida. This last-named section of the Invertebrata was found on a closer examination to represent their actual position in the zoological scale. On splitting one of the smaller flattened branches of the coral perpendicularly and parallel with its wider axis, I found that the entire coronid system was exposed to view. The little annelid fabricators, having an average length of one-fifteenth of an inch, wriggled into the water in every direction, a large number at the same time remaining passively in the tubular chambers which they originally constructed.

The most prominent external characters of the annelid of *Heliopora cerulea* consist of the bitentaculate head and six pairs of lappet-like branchiæ, which originate in segmental pairs on the dorsal surface and commence about the sixth segment posteriorly from the head. Fine isolated or paired setæ are developed in duplicate on the majority of the residual segments, and two brush-like fasciculi of closely adpressed setæ are conspicuous on the dorsal aspect of the penultimate and antipenultimate caudal segments. On my return to Brisbane a few weeks hence, I purpose preparing and remitting a more detailed account, with illustrations, of the organization of *Heliopora*. In the interim it has occurred to me that this brief announcement of its nature may prove of interest to many of your readers, more especially as it may assist in throwing fuller light on the affinities of the many fossil genera that have hitherto been affiliated with this type among the Cœlenterata, but which in common with *Heliopora* should probably find their true position among the more highly organized section of the Tubicolous Annelida.

W. SAVILLE-KENT,
Commissioner of Fisheries, Queensland.

Thursday Island, Torres Straits, June 18.

Chambers's "Hand-book of Astronomy."

As the writer of the article on "Spectroscopic Astronomy" in the above work, I should like to be permitted to comment upon two points wherein your reviewer has, though doubtless inadvertently, scarcely done me justice.

On p. 292 (NATURE of July 24) the reviewer says that I have "*selected* certain determinations and arranged them in parallel columns to demonstrate the efficiency of the method adopted." The reference is to the comparison which I gave of the results obtained by Dr. Huggins, Mr. Seabroke, and at Greenwich, for motions of stars in the line of sight. But I made no selection. I took *all* the stars that had been observed at two or more of these Observatories, and gave the mean of *all* the observations of each star. I might further add that I think your reviewer is scarcely fair in his description of the discordances of my observations: expressed in wave-length, the average difference from the mean is but a small fraction of a tenth metre. But this is an unimportant matter compared with the suggestion that I have published a "selected"—that is, a "cooked"—comparison.

Then your reviewer complains that I make no reference to Prof. Vogel's observations of Algol, whilst I give my own "later division" of my observations into groups. I made no reference to Prof. Vogel's observations, because they were not published until some considerable time after the final revise of my article had been passed for press; whilst, so far from my division of my observations into groups being later than Prof. Vogel's work, it was two full years earlier, having been communicated to the Royal Astronomical Society in January, 1888, by the Astronomer-Royal (see *The Observatory*, vol. xi. p. 109). I also gave my results in one of the Gresham Lectures, Easter, 1888.

E. W. MAUNDER.

Royal Observatory, Greenwich, S.E., August 1.

I REGRET that my words allowed the interpretation which Mr. Maunder points out, for I had no intention of insinuating that the comparisons were "cooked." What I take exception to is that, according to the values given, γ Cassiopeiæ has a motion in the line of sight of -12, although on February 19, 1887, Mr. Maunder determined it as $-54{\cdot}2$, and eight minutes afterwards as $+60{\cdot}9$; and again, β Pegasi is stated to have a motion in the line of sight of -8, although in November 1881 two determinations, made within ten minutes of each other, differed by nearly 114 miles per second. It would seem, therefore, that in making a tabular statement, even of the mean of such values found by different observers, the magnitude of the probable error should be mentioned; for, as I remarked at the time, "To one unacquainted with instrumental difficulties, the motion of stars in the line of sight would appear to be a quantity that may be determined with some accuracy," whereas this is not the case. I have no intention of questioning Mr. Maunder's skill as an observer, but the fact that the discordances, when expressed in wave-lengths, are very small, only supports my contention that, until more perfect instrumental conditions are possible, many of the values are useless, and their determination an affectation of accuracy.

Mr. Maunder has himself to blame for my want of information with respect to Algol. He gives no reference to the report of the remarks made by the Astronomer-Royal in January 1888, and his own comments, at the meeting of December 1889, upon Prof. Vogel's work, led me to suppose nothing had been done previously.

THE REVIEWER.

Gregory's Series.

GREGORY'S series, on which are founded nearly all the methods of obtaining the approximate value of π, is made to depend, in works on trigonometry, on De Moivre's theorem and results flowing from it.

The following does not require the use of $\sqrt{-1}$, but depends only on two things—that the circular measure of an angle and its tangent are practically equal when the angle is indefinitely small, and that $\tan(A - B) = \dfrac{\tan A - \tan B}{1 + \tan A \cdot \tan B}$.

Let

$$\tan\theta \equiv \tan(a_0 + a_1x + a_2x^2 + \&c.) = x;$$

$$\therefore \tan\{a_0 + a_1(x+h) + a_2(x+h)^2 + \&c.\} = x + h;$$

$$\therefore \tan h \cdot \{a_1 + 2a_2x + 3a_3x^2 + \&c. + \text{terms involving } h\text{, say H}\} = \frac{h}{1 + x(x+h)};$$

$$\therefore \frac{\tan h\{a_1 + 2a_2x + 3a_3x^2 + \&c. + H\}}{h(a_1 + 2a_2x + 3a_3x^2 + \&c. + H)} = \frac{1}{\{1 + x(x+h)\} \cdot (a_1 + 2a_2x + 3a_3x^2 + \&c. + H)}.$$

Let $h = 0$;

$$\therefore 1 = \frac{1}{(1 + x^2) \cdot (a_1 + 2a_2x + 3a_3x^2 + \&c.)}.$$

Equating coefficients of like powers of x,

$$a_1 = 1,\ a_2 = 0,\ a_3 = -\tfrac{1}{3},\ \&c.;$$

$$\therefore \theta = a_0 + x - \tfrac{1}{3}x^3 + \&c.,$$

where evidently $a_0 = 0$, or a multiple of π.

Taking $\theta = \dfrac{\pi}{4}$,

$$\frac{\pi}{4} = 1 - \tfrac{1}{3} + \tfrac{1}{5} - \tfrac{1}{7} + \&c.$$

R. CHARTRES.

The Perseid Meteor Shower.

WITH reference to the letter of Mr. Monck in NATURE of July 24 (p. 296), I would remark that his attempted explanation of the displacement in the Perseid radiant point is altogether futile. If your correspondent were better acquainted with the facts in detail, I think he would readily admit this.

My observations in this branch have been effected in the hope that they might prove useful, and I am sorry to see that Mr. Monck has so thoroughly misapprehended them. The shifting radiant of the Perseids is fully proved, and anyone who will take the trouble to watch the sky at the proper season may readily observe the fact for himself. W. F. DENNING.

Bristol, August 2, 1890.

COMPARISON OF THE SPECTRA OF NEBULÆ AND STARS OF GROUPS I. AND II. WITH THOSE OF COMETS AND AURORÆ.

I.

THE first step towards my present views as to the evolutions of the various groups of cosmical bodies was taken when one day I was attempting to trace the origin of the absorption flutings in stars of Vogel's Class III.*a*. So far, no one had endeavoured to trace their origin, all the work having been confined to the absorption *lines*. It is true that both Dr. Huggins and Vogel, as well as others, had published maps of the spectra of these stars, showing the absorption flutings as well as the lines, but the origins of the former were not inquired into.

It was at once perfectly obvious that among the chief absorption flutings were the most prominent of those seen in the spectrum of manganese at the temperature of the oxy-coal-gas flame—a temperature at which only one *line* is visible, while in the sun all the lines of manganese are visible. In order to investigate this further all the flutings seen when the principal metals were exposed to this temperature were mapped, with a view of determining whether any others besides those of manganese were visible in the stellar spectra. Several others, notably one of lead, were found to be present.

Here, then, was proof positive of low temperature: from solar absorption to the absorption of these stars of Class III.*a* we passed from phenomena which we can reproduce at the temperature of the arc to those visible at the temperature of the oxy-coal-gas flame.

It was next found that identical absorption phenomena are seen in comets long before they reach perihelion. This was a striking result, considering the vast difference in the way in which the phenomena of distant and near meteoric groups are necessarily presented to us; and bearing in mind that in the case of comets, however it may arise, there is an action which drives the vapours produced by impacts outward from the swarm in a direction opposite to that of the sun.

It must be a very small comet which, when examined spectroscopically in the usual manner, does not in consequence of the size of the image on the slit enable us to differentiate between the spectra of the nucleus and envelopes. The spectrum of the latter is usually so obvious, and the importance of observing it so great, that the details of the continuous spectrum of the nucleus, however bright it may be, are almost overlooked.

A moment's consideration, however, will show that if the same comet were so far away that its whole image would be reduced to a point on the slit-plate of the instrument, the differentiation of the spectra would be lost; we should have an integrated spectrum in which the brightest edges of the carbon bands, or some of them, would or would not be seen superposed on a continuous spectrum.

But another revelation still more startling was in store for me, when my assistants and myself had exhausted all the flutings then known to us as origins for the so-called dark bands which remained, and found that none would fit, and we seemed at the end of our tether.

My ten years' work on carbon made itself quite unconsciously felt at this juncture. It suddenly flashed upon me that the 517·2, 516·7, 516·6, 516·7, 517·1, &c., recorded by Dunér in his observation of α Orionis as the edge of a dark band, *could be nothing but the edge of the brightest band of carbon*, the bright cometary band *par excellence*, and therefore that these so-called stars not only resemble comets in their absorption flutings, as we now learn, but in their radiation flutings as well; in short, these stars *were* comets, with the difference—a trifling one from my then point of view—that they were not moving round our sun.

This surmise has since been abundantly confirmed. The dark band of Dunér is a *contrast band*—the spectrum looks dark there on account of the extreme brilliancy of the carbon fluting. The other carbon flutings were next sought for and easily found.

These "stars," then, instead of being like our sun, consisted of swarms of meteorites. We have in these bodies a spectrum integrating the *radiation* of carbon and the *absorption* of manganese and lead vapour, as in the case of some comets.

The law of parsimony compels us to ascribe the bright fluting of carbon in these "stars" to the same cause as that at work in comets, where we know it is produced by the vapours between the individual meteorites or repelled from them. Hence we are led to conclude that the absorption phenomena are produced by incandescent vapours surrounding individual meteorites which have been rendered intensely hot by collisions, while the carbon light comes from the interspaces.

I propose in the present paper to give a summary of the evidence of cometary kinship, so to speak, among the other cosmical bodies; and I shall follow this by an historical statement showing how previous observers have suspected the presence of carbon in "stars."

First as to cometary kinship.

The discussion of cometary spectra which I communicated to the Royal Society in November 1888 (Roy. Soc. Proc., vol. xlv. pp. 159–217), contained, among other matters, conclusions which have a special bearing on the relations of their spectra to those of other bodies.

It is obviously desirable to compare this material with the more complete lists of lines which I have now obtained from a very thorough search after all the observations hitherto made of other groups of celestial bodies, since such a comparison—a much more complete one than was possible in the first instance—would strengthen or weaken my hypothesis according as the increased area of observation increased or decreased the number of coincidences in the spectra of the various groups.

The more the coincidences are intensified the greater is the probability that comets, nebulæ, stars with bright lines, stars with mixed flutings, and the aurora have a common origin, independent of the chemical origins which have been assigned to the various lines by laboratory observations.

In the tables which follow, the individual observations are not given, but under each heading all the lines or flutings which have been recorded find place.

I. *Comparison of Comets and Nebulæ.*

We may conveniently begin with a comparison of comets and nebulæ. The Great Comet of 1882 and Comet Wells, when near perihelion, are excluded from the list of cometary lines and flutings, as their temperature was too high for fair comparison with most of the nebulæ and other low temperature phenomena.

In cases where any of these higher temperature lines correspond to lines in the comparison spectrum, however, they have been added to the list of cometary lines, in

brackets, as sometimes the phenomena compared may attain a temperature slightly higher than that of comets at mean temperature.

For the nebulæ, all the lines recorded in the visible spectrum by Messrs. Huggins, Vogel, Copeland, Fowler, and Taylor, are given. The list of lines has been considerably extended since my preliminary discussion of the spectra of nebulæ in November 1887. D_3 and a line at 447 have been observed in the spectrum of the nebula in Orion by Copeland, and Mr. Taylor has also recorded D_3 and lines, or remnants of flutings, at 559 and 520. In the nebula in Andromeda, carbon flutings and the lead flutings at 546 have been observed by Mr. Fowler and confirmed by Mr. Taylor; since these observations were made, I find that Vogel (*Bothkamp, Beob.*, Heft 1, 1872, p. 57) observed a line at 518, probably carbon 517, in nebulæ numbered in Sir J. Herschel's General Catalogue 4234, 4373, and 4390.

Other nebula lines with which I was not previously acquainted are 479, 509, and 554. All these lines were observed by Vogel in the nebula G.C. 4378 (*Bothkamp, Beob.*, Heft 1, 1872, p. 57).

With reference to the appearance of D_3 in nebulæ and bright-line stars, I wrote, in November 1887 (Roy. Soc. Proc., vol. xliii. p. 139):—"It is right that I should here point out that some observers of bright lines in these so-called stars have recorded a line in the yellow which they affirm to be in the position of D_3; while, on the other hand, in my experiments on meteorites, whether in the glow or in the air, I have seen no line occupying this position.

"I trust that some observer with greater optical means will think it worth his time to make a special inquiry on this point. The arguments against this line indicating the spectrum of the so-called helium are absolutely overwhelming. The helium line so far has only been seen in the very hottest part of the sun which we can get at. It is there associated with *b*, and with lines of iron which require the largest coil and the largest jar to bring them out, whereas it is stated to have been observed in stars where the absence of iron lines and of *b* shows that the temperature is very low. Further, no trace of it was seen in Nova Cygni, and it has even been recorded in a spectrum in which C was absent, and once as the edge of a fluting.[1]

"It is even possible that the line in question merely occupies the position of D_3 by reason of the displacement of D by motion of the 'stars' in the line of sight. On this point no information is at hand regarding any reference spectrum employed.

"*If, however, it should eventually be established that the line is really D_3, which probably represents a fine form of hydrogen, it can only be suggested that the degree of fineness which is brought about by temperature in the case of the sun, is brought about in the spaces between meteorites by extreme tenuity.*"

The observations of Dr. Copeland (*Monthly Notices R.A.S.*, vol. xlviii. p. 360), have now, I think, established the identity of the yellow line, in the nebula of Orion at all events, with D_3. In a letter to Dr. Copeland, I suggested that the line at 447 was in all probability Lorenzoni's *f* of the chromosphere spectrum, seeing that it was associated both in the nebulæ and chromosphere with hydrogen and D_3. This he believes to be very probable. The line makes its appearance in the chromosphere spectrum about 75 times to 100 appearances of D_3 or the lines of hydrogen.

The association of the line at 447 with D_3 therefore strengthens the view that there is an action in space, away from condensations, whereby matter is reduced to its finest forms.

[1] ". . . . The spectrum is very bright; two strong bands are seen in the red, then the D line, followed by a bright line (D_3) as the edge of a band. . . . ." (Konkoly, "Neuer Stern bei χ Orionis," *Astr. Nachr.*, No. 2712).

With regard, then, to the comparison of the spectra of comets and nebulæ the case stands as follows:—

Comets.	Nebulæ.	Probable Origins.	λ of Probable Origins.
—	411	H	4101
431	—	CH	431
—	434	H	434
—	447	?	—
468–474	468–474	C (hot)	468–474
—	479	?	—
483	—	C (cool)	483
486	486·3	H	486
—	495	?	—
500	500	Mg	500
—	509	?	—
517	517	C (hot)	517
519	—	C (cool)	519
521	520	Mg	521
[527]	527	Fe	527
546	546	Pb	546
—	554	?	—
558	559	Mn	558
561	—	C (cool)	561
564	—	C (hot)	564
568	—	Pb, Na	568
—	5872	? (D_3)	—

The table shows that there are many striking similarities between the two spectra, and there is no doubt that many of the lines are identical. The flutings of hot carbon, for example, are common to both, as are also the flutings of magnesium, manganese, and lead. The hydrogen line 486 has only been seen in one comet, namely, Comet III. 1880, by Konkoly ("O'Gyalla Observations," 1881, p. 5.)

Other flutings and lines again are special to comets and others to nebulæ. Thus, there are practically no indications of hydrogen in comets, although the hydrogen lines are amongst the brightest in nebulæ. Again, the lines 447, 479, 495, 509, and 554 are seen in nebulæ, but not in comets. On the other hand, the cool carbon flutings and the fluting at 568 are seen in comets, but not in nebulæ. Most of these apparent discrepancies are explained by a consideration of the differences in the conditions of comets and nebulæ. It must be remembered that in the case of comets there is an action which repels the vapours produced by collisions, and the vapours first affected will, of course, be those which are least dense. Hydrogen will thus be repelled from the comets, whilst the denser vapours of magnesium and carbon remain. There is then a good reason why hydrogen lines should *not* be seen in cometary spectra. As there can be no such repulsion in the sparse swarms which constitute nebulæ, hydrogen lines are seen in them.

Two other lines special to nebulæ are 5872 and 447, to which reference has already been made. The evidence tends to show that D_3 and *f* are finer vapours than hydrogen, and hence there is even greater reason for the absence of these lines from cometary spectra, even were the temperature higher, than for the absence of the lines of hydrogen.

The line at 527 is probably the iron line E; this was seen in the hotter comets, namely, Comet Wells and the Great Comet of 1882, so that there is no discordance with regard to the appearance of this line. The other lines special to nebulæ are 479, 495, 509, and 554; but as no origins for these have yet been determined, it is not possible to explain their absence from cometary spectra. It is not improbable that 554 is an error in measurement for the manganese fluting at 558, the latter having been recorded by Mr. Taylor in the nebula of Orion.

The apparent absence of the cool carbon flutings from nebulæ is in all probability due to insufficient observations, as indicated by the discussion of comets. The lowest

temperature (magnesium) and the hot carbon stages of comets are both represented in nebulæ, and the intermediate cool carbon stage is therefore not likely to be entirely absent.

The absence of the hot carbon fluting at 564 from the spectra of nebulæ may possiby be due to two causes. It is much fainter than either 517 or 468–474, and may have escaped notice on that account; or, as in the nebula in Andromeda, it may be masked in the same way as in comets.

It is suggested that the ordinary nebulæ are not hot enough to give the line or fluting at 568, but it appears when the swarms become more condensed—that is, in bright-line stars. The absence of 568 is therefore probably due to the low temperature of nebulæ.

II. *Comparison of Comets and Auroræ.*

If we exclude the exceptional cases of Comet Wells and the Great Comet of 1882, the number of lines and flutings recorded in comets is small, and therefore only the most general list of auroral lines must be taken for comparison. It would be unfair, for example, to take the long list of lines given by Gyllenskiöld. The lines stated are taken from the table which I gave in a note in January 1888 (Roy. Soc. Proc., vol. xliii. p. 321) which has since been slightly rearranged before taking the means.

Comets.	Auroræ.	Probable Origins.	λ of Probable Origins.
—	411	H	4101
[426]	426	?	?
431	431	CH	431
—	435	H	434
468–474	474–478	C (hot)	468–474
483	482	C (cool)	483
486	486	H	486
500	500	Mg	5006
517	517	C (hot)	517
519	519	C (cool)	519
521	522	Mg	521
—	531	?	—
—	535	Tl	535
—	539	Mn	540
546	545	Pb	546
558	558	Mn	558
561	—	C (cool)	561
564	—	C (hot)	564
568	—	Pb, Na	56[illegible]
—	606	?	—
[615]	620	Fe	615
—	630	?	—

Here, again, it will be seen, that there are many striking coincidences. The hydrocarbon fluting at 431 and the hot and cool carbon flutings at 468–474, 483, 517, and 519 are common to both. The flutings of magnesium 500 and 521 and the flutings of lead and manganese at 546 and 558 are also common. The iron fluting at 615 is not seen in comets at ordinary temperatures, but since it was recorded in the Great Comet of 1882, it has been added, in brackets, to the list of cometary flutings. The line at 426, which was seen in Comet Wells, has also been added. It will be noted also that there are apparent discrepancies; some lines appearing only in comets and others only in auroræ. The explanation of the absence of hydrogen lines from comets which has already been given applies equally in this case. As there is no repulsion in the aurora similar to that exercised upon comets by the sun, there is no reason for the absence of hydrogen. In the aurora the hydrogen lines may also be produced partly from aqueous vapour. The citron carbon flutings 561 and 564 have not been recorded in the aurora, although they are often seen in comets; their apparent absence from the aurora is probably because they fall in the brightest part of the continuous spectrum, and are consequently masked.

The lines special to auroræ are 531, 535, 539, 606, and 630.

III. *Comparison between Comets and Bright-line Stars.*

In the Bakerian Lecture for 1888 I gave a complete discussion of the spectra of bright-line stars, as far as the observations then went, and the conclusion arrived at was that they are nothing more than swarms of meteorites a little more condensed than those which we know as nebulæ. The main argument in favour of this conclusion was the presence of the bright fluting of carbon which extends from 468 to 474. This, standing out bright beyond their short continuous spectrum, gives rise to an apparent absorption-band in the blue. The varying measurements made by different observers may possibly have thrown a little doubt upon the conclusion that the bright band was due to carbon, but recent observations at Kensington have placed this beyond doubt. Direct comparisons of the spectrum of all the three stars in Cygnus with the flame of a spirit lamp have been made by Mr. Fowler, and these showed an absolute coincidence of the bright band in the stars with the blue band of carbon seen in the flame. It was found quite easy to get the narrow spectrum of the star superposed upon the broader spectrum of the flame, so that both could be observed simultaneously.

Other evidence of carbon flutings was shown by slight rises in Vogel's light-curves near 517 and 564. These, however, could not be as well seen as the band in the blue, because they fall on the bright continuous spectrum from the meteorites. In the stars in Cygnus, Mr. Fowler detected brightenings near 517, and perfect coincidences were found with the fluting at 517 in the spirit-lamp flame. In this case both 517 and 468–474 were simultaneously seen to be coincident with flame-bands.

Measurements were made of the brightenings in the spectrum of γ Cassiopeiæ by Mr. Fowler on September 18, and these were also found to be coincident with the carbon flutings 517 and 468–474; the citron fluting at 564 was not seen. It may be remarked that C, F, and D_3 were seen very bright.

The conclusions drawn from my suggestions as to the presence of carbon, as well as hydrogen, in bright-line stars, are therefore strengthened.

In the following table, all the lines and flutings recorded in bright-line stars, with the exception of γ Cassiopeiæ, are given. The lines recorded by Sherman in γ Cassiopeiæ have not yet been confirmed.

Comets.	Bright-line Stars.	Probable Origins.	λ of Probable Origins.
—	4101	H	4101
431	—	CH	431
—	434	H	434
468–474	468–474	C (hot)	468–474
483	—	C (cool)	483
486	486	H	486
500	—	Mg	500
—	507	? Cd	508
517	517	C (hot)	517
519	—	C (cool)	519
521	—	Mg	521
[527]	527	Fe	527
—	540	Mn	540
546	—	Pb	546
558	558	Mn	558
561	—	C (cool)	561
564	564	(C hot)	564
568	568	Pb, Na	568
[579]	579	Fe	579
—	5872	? (D_3)	—
[589 (D)]	589	Na (D)	5889, 5895
—	635	?	—

The coincidences here are between the flutings of hot carbon, manganese 558, and lead or sodium 568. D has only been seen bright in one of the stars (γ Argûs), which is probably one of the hottest; since D was seen bright in two of the hottest comets, I have inserted it in the list of cometary lines and flutings, and [527] and [579] are added for the same reason.

Although nine lines or flutings are common to comets and bright-line stars, six occur in comets which do not appear in bright-line stars, and five in bright-line stars which do not appear in comets.

The apparent absence of hydrogen from comets has already been referred to, as well as the absence of D_3. The cool carbon flutings are not seen in the bright-line stars because the temperature is too high, and the line at 500 is absent for the same reason; 521 is probably also absent because of the higher temperature. The lead fluting at 546 may be masked by continuous spectrum in the bright-line stars; at all events, it appears as an absorption-band when the swarms further condense. Besides the hydrogen and D_3 lines, the lines 507, 540, and 635 appear in bright-line stars, but not in comets.

IV. *Comparison of Comets and Stars of the Mixed Fluting Group.*

In the Bakerian Lecture I also gave evidence to show that stars of Group II. (Vogel's Class III.*a*) are of a cometary character, and a little more condensed than the bright-line stars. The ground on which this conclusion was arrived at was the probable presence of bright carbon flutings, in addition to the metallic absorptions. Observations of α Herculis and Mira Ceti by Mr. Fowler at Kensington and by myself at Westgate-on-Sea have fully confirmed this view. The rapid increase of brilliancy of the flutings of Mira at its maximum in 1888 left little doubt in my mind that they were due to carbon, and Mr. Fowler's comparisons showed perfect coincidences with the carbon flutings, with the dispersion of two prisms of 60°.

Some of the origins which I suggested for the dark bands have also been tested by direct comparisons. Dunér's bands 4 and 5 were found to be coincident with the manganese and lead flutings at 558 and 546 respectively, and band 3 was found to be coincident with the manganese fluting about 586.

Mr. Maunder observed the spectrum of α Orionis on December 16, 1887, and made comparisons with the spectra of carbon, sodium, and manganese, as given by a Bunsen flame. He states the results as follows ("Greenwich Observations," 1887, p. 22):—"The carbon band at 5164 was coincident (within the limits of observation with this dispersion) with the bright space towards the blue of Band VI. (Dunér's band 7), and the sodium lines were clearly represented by two dark lines near the middle of Band II. (Dunér's band 3), but the two manganese bands observed, not only did not coincide with any great band of the spectrum, but were very far distant from any of them. There were, indeed, faint lines about the neighbourhood of either manganese band, but the entire spectrum is full of such lines, and no fluting, nor anything corresponding to one, could be detected near the place of these two bands. A third manganese band was very close to Band II. (Dunér's band 3) of the stellar spectrum." On the other hand, Vogel measured the position of the sharp edge of a fluting in α Orionis as 559·1, and Dunér's measures for the same vary from 557·5 to 559·3, none of which can be described as "very far distant" from the manganese fluting near 558. Mr. Maunder's observation can only be explained by assuming that the band in question is variable. This might be produced by variations in the intensity of the carbon flutings; the manganese fluting falls on the carbon fluting near 564, and, according to their relative intensities, the manganese fluting will be visible or will be masked by the carbon. According to Gore, the star was at a minimum in December 1887.

The fluting near 586 corresponds to Dunér's band 2, for which Dunér measures wave-lengths varying from 585·4 to 586·1. It apparently escaped Mr. Maunder's notice, at the time he made his observations, that no reference was made in my paper of November 1887 to any band in the star spectra which fell near the third fluting of manganese near 535. The first two flutings, near 558 and 586, fell so near to two of the dark bands in the spectra of the stars of Group II. that there was strong ground for believing them to be due to manganese. This has since been abundantly confirmed by Mr. Fowler's direct comparisons of the manganese flutings with the spectra of several stars of the group.

Under the heading of "Dunér's Bands" I give the mean wave-lengths measured by Dunér for the dark bands, and the limits of the bright spaces which are due to carbon.

The figures first given refer to the sharp edges of the flutings; the other figures indicate approximately where the flutings fade away.

This comparison shows that there is a very close relation between comets and Group II. independent of the probable origins suggested. Bright carbon flutings, the manganese fluting at 558, the lead fluting at 546, the iron fluting at 615, and the magnesium fluting 521, are common.

Comets.	Dunér's Bands.		Probable Origins.	λ of Probable Origin.
—	461–451	Bright space	C_B	460–451
—	461–473	(10) Dark space	—	—
468–474	472–476	Bright space	C (hot)	468–474
—	476–486	(9) Dark space	—	—
483	—	—	C (cool)	483
—	495–486	? Bright fluting	?	—
500	495–502	(8) Dark fluting	Mg	500
517	516–502	Bright fluting	C (hot)	517
519	—	—	C (cool)	519
521	516–522	(7) Dark fluting	Mg	521
—	524–527	(6) Dark fluting	Ba (2)	526
546	544–551	(5) Dark fluting	Pb	546
558	559–564	(4) Dark fluting	Mn (1)	558
561	—	—	C (cool)	561
564	—	—	C (hot)	564
—	585–594	(3) Dark fluting	Mn (2)	586
[615]	616–630	(2) Dark fluting	Fe	615
—	647–668	(1) Dark fluting	?	—

The cool carbon flutings are seen in comets, but not in stars of Group II. the reason being that the temperature is too high. The hot carbon fluting at 564 is in all probability present in stars of Group II., but is always masked, in some cases by continuous spectrum, and in others by the absorption fluting of manganese, which is nearly coincident with it.

The line, or probably fluting, at 495 has not yet been recorded in comets, but its association with the fluting at 500 in Nova Cygni indicates that its apparent absence is entirely due to incomplete observations.

The second fluting of manganese, near 586, though one of the most prominent in stars of Group II., has not been observed in cometary spectra, probably because there is not sufficient continuous spectrum from the sparse meteoritic background of the comet to produce the absorption of more than the first fluting of manganese.

Dunér's band 1, 647 to 668, has not yet had an origin assigned to it.

J. NORMAN LOCKYER.

(To be continued.)

ON THE STUDY OF EARTHQUAKES IN GREAT BRITAIN.[1]

THERE can be little doubt that the more important contributions to our knowledge of earthquakes must be made in countries like Switzerland, Italy, and Japan; countries where earthquakes are frequently occurring, where, occasionally, they are so disastrous as to arrest universal attention, and where, at the same time, there are many skilled observers aided by a sympathetic and intelligent public. In England, as every strong shock shows, there is no lack of observers. But our earthquakes that are strong enough to attract general notice within the disturbed area are few and far between. If we exclude special districts, like Comrie and the Durham coast, we shall probably be well within the mark in stating the average number recorded as less than one a month.

The number of earthquakes that occur in Great Britain must, however, be far greater than this. From various causes, many shocks that are felt are never placed on record. Others, again, that might be felt, must certainly pass unnoticed, for, wherever seismic studies are newly organized, it is found that people become educated in detecting earthquake-shocks. But, however skilful observers may become, there must always be a large number of shocks that never could be felt, either from the small amplitude or the long period of their vibrations. Even in Tokio, where they talk about earthquakes as we in England talk about the weather, "the majority of shocks pass unfelt by people, while seismographs register them sufficiently to allow measurements" (S. Sekiya, Japan Seism. Soc. Trans., vol. x. p. 59).

There is every reason to conclude, then, that, with the aid of simple time-recording seismoscopes, the earthquakes of Great Britain would be found sufficiently numerous to repay a more careful and systematic study. That we shall have to be content, as a rule, with observing shocks that would elsewhere be considered slight is evident of course; but in their very feebleness we possess advantages which are not afforded by severer shocks of other lands. Not only are the phenomena much less complex; but, not being unnerved by danger, the observer is able to concentrate his attention on them more calmly and completely. Still more important is the fact, and in this lies their greatest value, that, the smaller the area disturbed, the more nearly can the position of the epicentrum be determined. If, as is frequently the case, the shock be felt only within a small circular area, we cannot be far wrong in regarding the centre of that area as the approximate site of the epicentrum. And thus we easily obtain the solution of what, in a great earthquake, is one of the most difficult and important of the problems to be attacked.

Methods of Study in Great Britain.—Owing to the feebleness of our shocks, and their comparative rarity in a given district, the methods of study employed by us must clearly be different from, and inferior to, those adopted with such signal success in Italy and Japan. We can hardly expect, for instance, that costly recording instruments will be widely used in this country; for, even in Italy, as Prof. de Rossi points out (*Bull. del Vulc. ital.*, anno iv., 1877, p. 5), it has been found better to have a large number of observatories containing cheap and simple instruments, than a few equipped with seismographs more perfect and refined.

If, on the one hand, then, our methods of earthquake study are limited by the nature of the shocks we experience, on the other we possess advantages, apart from those already mentioned, that are more or less wanting in regions where the phenomenon attains a more destructive and interesting development. For instance, most parts of England at any rate are so densely populated that we are able, almost wherever a shock occurs, to procure a large number of observations of very considerable value. And again, in the ease and accuracy with which we can regulate our clocks in the neighbourhood of every large town, we have an aid in our work which is as valuable as it is rare in foreign countries. These two facts in particular I mention here because they form the foundation of our two most promising methods of investigation.

Looking at earthquakes chiefly from a geological point of view—that is, regarding them as mere incidents, but at the same time delicate indices, of the progress of terrestrial evolution—the prime object of our inquiries is in every case to determine the position of the epicentrum, and, if possible, that of the seismic focus. For this purpose, we have three methods at our disposal, depending severally upon observations of the direction, intensity, and time of occurrence, of the shock in different parts of the disturbed area.

The first method is interesting historically from its having been used by Mallet in the earliest scientific study of an earthquake. But modern seismologists have with good reason generally discarded it; and, in any case, it could hardly be employed with success in this country.

The method of intensities is far more trustworthy, and is attended with good results whenever the observations are sufficiently numerous and made at places that are fairly evenly distributed over the disturbed area. With the aid of such a scale as that drawn up by MM. de Rossi and Forel, the intensity of the shock at any point may be roughly estimated. Then, drawing lines including all places where the intensity is at or above a certain degree of the scale, we obtain a series of lines of equal intensity (isoseismal lines), which, closing in towards the epicentrum, enable its position to be approximately determined. For the slighter shocks that we experience, it would be difficult to over-estimate the value of this method, the only one that in certain cases can be applied.

The last of the three methods, I think I may say, is still upon its trial; and if, so far, it has not yielded all the results that are to be expected from it, I believe the reason is that it has not yet been attempted in a country where the conditions are so favourable for its application as they are in many parts of England. What we require for the purpose is, not a network of time-recording instruments extending over the whole country, so much as a moderate number suitably placed and regularly observed in specially selected districts. If, by means of these instruments or otherwise, the times of a shock can be ascertained with accuracy at five or more places, these, under certain conditions, are theoretically sufficient to determine the position of the epicentrum, the depth of the seismic forces, the velocity of the earth-wave, and, consequently, the time of occurrence at the focus. And it should be noticed that time-recorders in Great Britain are practically free from the objection which attends them in Japan and other regions where earthquakes frequently last for one or several minutes. For, in such cases, the character of the shock varies so greatly throughout the disturbed area, that it need not, and probably will not, be one and the same vibration which is registered in different places, and considerable errors may thus be introduced.[1] If, then, we remember that our earthquake shocks seldom last for more than a few seconds at most, and that, in many parts of England and some parts of Scotland, it should be possible to ascertain the time of occurrence correctly to within a small fraction of a minute, I think there can be little doubt that, for all but the slightest shocks, a most fruitful method of earthquake

[1] A Paper by Charles Davison, M.A., King Edward's High School, Birmingham; read before the Birmingham Philosophical Society on February 5, 1890. A few passages added since the paper was read are enclosed in brackets.

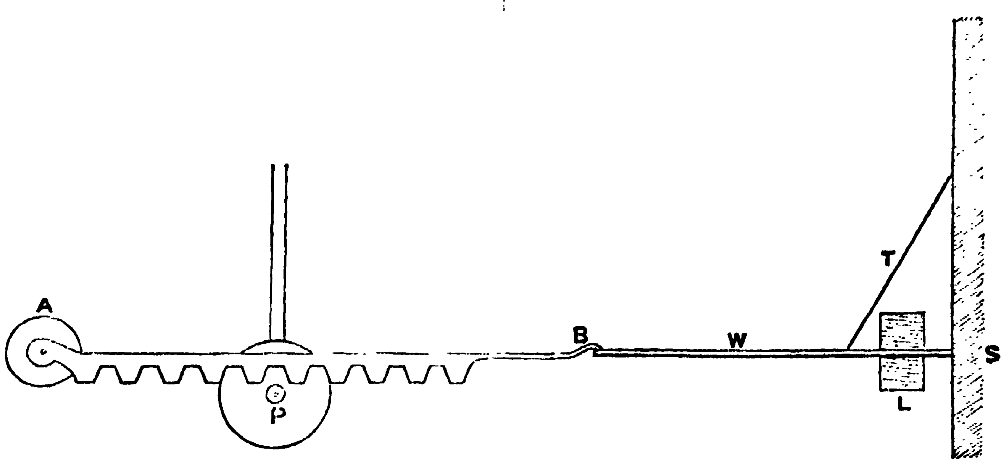
[1] E. Knipping and H. M. Paul, Japan Seism. Soc. Trans., vol. vi. p. 37; also J. A. Ewing, vol. iii. pp. 63–64, and J. Milne, vol. iv. pp. 100–101.

study in this country would be a system for securing accurate time-records whenever a shock is felt.

Seismoscopes.—A large number of simple and inexpensive seismoscopes have been devised and used for recording the time of occurrence of an earthquake shock; but it is difficult to find one that in all respects is thoroughly satisfactory.[1] To be so, they should fulfil the following conditions:—They should be inexpensive, simple in their construction, easy to arrange, and require little attention when once erected. They should record the occurrence of shocks and tremors with equal facility in whatever direction they may arrive; and they should be equally sensible in recording a feeble shock. It is very desirable also that they should be of similar construction, at any rate in a given district, if not throughout the whole country, so that observations from different places may be rightly comparable.

Again, in countries where earthquakes are frequent, and where the shocks may succeed one another at short intervals, it is important that the record should be made without stopping the clock. In Great Britain, however, our catalogues show that, except at Comrie, it is not usual for sensible earthquakes to follow one another rapidly, and it is therefore worth while considering whether, on account of their much greater cheapness and simplicity, it might not be well to avail ourselves in this country of clock-stopping apparatus. Such instruments, are, of course, defective in that, until re-set, they are incapable of recording a second earthquake. But they possess a compensating advantage in the accuracy with which it is possible to time the occurrence of a shock.

Clock-stopping Apparatus.—As it is possible to make with ease, and at little cost, an extremely delicate apparatus for stopping a clock at the moment of a shock, I quote the following description of one devised by Prof. J. Milne (Japan Seism. Soc. Trans., vol. iii. pp. 61–62):— is the pendulum of a clock with a small piece of wire standing out at right angles to its face. . . . This wire, as the pendulum swings, passes beneath a series of teeth cut in a strip of wood lightly hinged at A and terminating at the other end, B, with a piece of stiff wire. . . . If such a contrivance is allowed to fall, the teeth catch on the projecting pin of the pendulum, and it may arrest it at any portion of its swing." The arrangement which, at the time of an earthquake, allows the toothed lever to fall "consists of a piece of stiff wire, W, on which, near to one end, is a small cylinder of lead, L. The short end of this wire is pointed, and rests on a pivot-hole made in the head of a drawing-pin pressed into the side of the clock-case, S. To prevent this wire from falling, it is held up by a small silk thread, T, fastened to a second drawing-pin. As suspended, it is very unstable, and, instead of remaining at right angles to the clock-case, it swings round against it. When, however, the wire, B, rests on the end of W, it retains its position, as shown in the figure."



This instrument is so sensitive that it is difficult even to shut the clock-case without stopping the clock. The reason of this appears to be "that, if the clock-case receives a small displacement at right angles to W, the weight remains steady by its inertia, whilst the long arm of W in contact with B multiplies the initial motion" approximately in the proportion of the length of the long to that of the short arm of W.

It would appear that a displacement parallel to the wire W would not give this multiplication; but, practically, Mr. Milne observes, "it seems impossible to give a motion in that direction to which the apparatus does not seem to be just as sensible as to a motion in any other direction. The only other motion which does not result in stopping the clocks appears to be a *very slow* easy swing;" and thus the instrument will probably be incapable of recording the occurrence of the dying-out vibrations of a very distant shock.

The instrument may be placed in a cellar or out-house, or out of doors under the cover of a close-fitting box. A strong stake should be driven into the ground, to the depth of two or three feet, the floor, if any, being removed for a few inches round the stake to prevent the instrument being disturbed by the vibrations of the house. The clock-case should then be screwed firmly to the stake.

If several of these instruments are erected in a district, they should be placed at distances of not less than 5 to 10 miles apart.[1] The sites selected should, if possible, be free from the vibrations of passing carts and trains. If two or three of these record the occurrence of a shock at very nearly the same instant, it may be inferred that the disturbance is not accidental in its origin, and the inference will be strengthened if several instruments closely agree in their indications. But a record from one alone must obviously be regarded as doubtful, if all the others were at the time in good working order.

Suggestions for the Observation of Earthquakes (*without the use of special instruments*).—Lists of questions for aid in the study of earthquakes have been drawn up by Prof. Heim and Prof. Milne.[2] The following questions are founded partly on these lists, but chiefly on the accounts of earthquakes in different places, and especially in this country. It is hardly necessary to insist that all notes should be written down on the spot, or as soon after the shock as possible; but it may be useful to remark that it is often just as important to note when a given phenomenon is *not* observed as to describe it fully

[1] A Committee of the British Association is at present considering the form of seismoscope most suitable for use in this country.

[1] If the clock be carefully rated, it should be possible to obtain the time of a shock correct to a tenth of a minute. The velocity of earth-waves is subject to wide variations, even in traversing the same rocks; but, taking it at 1000 feet per second, it follows that the earth-wave will pass over more than a mile in one-tenth of a minute. A good deal more than a mile, then, should separate every pair of stations where seismoscopes are placed.

[2] A. Heim, "Die Erdbeben und deren Beobachtung"; *Arch. des Sc. phys. et nat.*, 3me pèr. t. iii. pp. 286–7; Fouqué, "Les Tremblements de Terre," pp. 133–4; Japan Seism. Soc. Trans., vol. i. part ii. pp. 3–4.

when it is observed. This applies particularly to the mere fact of the perception of the shock, as a knowledge of the places where it is just not felt is of service in enabling us to determine the boundary of the disturbed area.

The questions are arranged in the following sections: A, for places where the shock is felt; B, for those where it is not felt; and C, inquiries to be made after the shock. In each case, the questions to which it is most important that answers should be given are marked with an asterisk.

A.—For Places where the Earthquake is felt.

1.—*Place of Observation.*

* (*a*) Its name and position.

(*b*) Nature and form of the surrounding ground, especially with reference to its geological structure and the neighbourhood of mountains, rivers, cliffs, &c.

2.—*Situation of Observer.*

* (*a*) Whether indoors or in the open air; if indoors, on which floor of the house.

(*b*) If indoors, the direction of the street or of the longer axis of the house (if detached).

* (*c*) How occupied at the moment of the shock—lying down, working, &c.

3.—*Time of Occurrence.*

* (*a*) Time at which the shock was felt; if possible to a tenth of a minute.

* (*b*) Is the time given the correct time obtained after comparison with an accurately rated chronometer? and, if so, how long after the shock was the comparison made, and how is the chronometer regulated?

4.—*Nature of Shock.*

* Describe the nature of the shock as closely as possible, stating especially: (*a*) the number of the more prominent vibrations; (*b*) their relative intensity; (*c*) whether there was any tremulous motion before or after the vibrations; (*d*) whether any vertical motion was perceptible; [(*e*) whether, in the latter case, the movement in the principal vibration was first upwards and then downwards, or *vice versâ*].

5.—*Duration of Shock.*

* Total duration, exclusive of that of the sound phenomena (stating whether estimated, or determined by watch).

6.—*Intensity of Shock.*

* Was the shock strong enough (*a*) to make windows, doors, fire-irons, or crockery, &c., rattle; (*b*) to cause the chair or bed on which you were resting to be perceptibly raised or moved; (*c*) to make chandeliers, pictures, &c., swing, or to stop clocks; (*d*) to overthrow ornaments, vases, &c., or cause plaster to fall from the ceiling; (*e*) to throw down chimneys or make cracks in the walls of buildings?

7.—*Direction of Shock.*

(*a*) Direction of the principal shock or shocks.

(*b*) Means by which the direction was ascertained.

(*c*) Was any change of direction perceptible during the earthquake?

8.—*Sound-Phenomena.*

* (*a*) If any rumbling sound was heard at the time of the shock, what did it resemble?

[* (*b*) Did the sound end abruptly, or die away gradually?

* (*c*) Did the sound become deeper or higher towards the end?]

* (*d*) Did it precede, accompany, or follow the shock (Times useful, especially the intervals between the beginning of the shock and of the sound, and between the ending of the same; stating whether estimated, or determined by a watch.)

* (*e*) Duration (given by 5*a* and 8*b*, if not determined separately).

9.—*Effect on the Water of Ponds, &c.*

Were any movements observed in the water of ponds, rivers, lakes, or the sea, at, or shortly after, the time of the shock; if so, of what kind?

Accessory Shocks.

* Were there any slight shocks preceding or following the principal shock or shocks? If so, a list of these, with the place of observation, time of occurrence, and answers to any of the above questions, would be of great value.

B.—For Places where the Earthquake is not felt.[1]

1.—*Place of Observation.*

* (*a*) Its name and position.

* (*b*) Nature and form of the surrounding ground, especially with reference to its geological structure and the neighbourhood of mountains, rivers, cliffs, &c.

2.—*Situation of Observer.*

* (*a*) Whether indoors or in the open air; if indoors, on which floor of the house.

* (*b*) How occupied at the moment of the shock—lying down, working, &c.

C.—Inquiries to be made after the Shock.

1.—*Damage to Buildings.*

(*a*) Nature of the building damaged.

(*b*) Situation to the building, direction of its longer axis; neighbourhood to the edge of a cliff or bank, and on which side of this it lies; nature of the rock on which it rests.

(*c*) If any cracks formed, state in which walls; the direction and width of the cracks, and the points from which they start (sketches useful).

(*d*) If it is noticed that some walls are much damaged, while others at right angles to those are but little affected, what are the directions of these walls?

2.—*Rotation of Objects.*

* (*a*) If objects, such as chimneys, grave-stones, gate-pillars, &c., have been rotated on their bases during the shock, describe the initial and final positions of the objects (sketches useful); or state the direction and amount of the rotation (looking down on the object from above, is the direction the same as that in which the hands of a watch rotate, or opposite to that direction?).

(*b*) Is there any evidence of rotation in bodies with a circular base?

3.—*Effects on the Ground, Springs, &c.*

(*a*) Were any fissures or cracks formed in the ground? If so, state their length, width, depth, and direction, the nature of the ground in which they occur, and their relation to neighbouring cliffs, banks, &c.

(*b*) Was the height, quantity, or temperature of the water in springs affected by the shock?

4.—*Observations in Mines.*

If the earthquake was felt in a mining district, inquiries should be made as to the nature of the shock and of the sound-phenomena when observed by men in the mines; the depth of the workings in such cases, &c.

[1] [The value of observations under this heading would be greatly increased if they are the result of numerous inquiries made in a district.]

5.—*Records of Self-registering Instruments.*

* An examination should be made of the records of self-registering instruments within or near the disturbed area—particularly of recording barometers, magnetic and tidal apparatus—with a view to determine the effects of the shock on these instruments, and also to ascertain by their means the exact time of occurrence.

While answers to any of the above questions would be useful in the study of an earthquake, especial pains should, if possible, be taken to determine accurately the time at which the principal shock occurs. Immediately it is felt, the time should be noted to the nearest second, and written down at once, a few seconds (to be ascertained by trial) being allowed for taking out the watch and reading off the time. As soon afterwards as possible, the watch used should be compared with an accurately regulated clock. But if this cannot be done, if the record cannot be relied on as correct to within a small fraction of a minute, a less close approximation cannot as a rule possess much value. The chief use of such a record is then to determine the epoch of the shock; and, in a matter of this kind, when two consecutive shocks in a given district may be separated by an interval of several years, a question of a few minutes, more or less, is of very little moment.

Next in importance to time-observations are those on the intensity of a shock. Without the aid of delicate instruments it is of course impossible to estimate the intensity with accuracy. But good results have been obtained by the use of a rough scale, according to which the intensity is determined by its effect on men and their dwellings. The following is the Rossi-Forel scale,[1] which is widely adopted by Italian and Swiss seismologists:—

Rossi-Forel Scale of Intensity.

I. Micro-seismometric shock: noted by a single seismograph, or by some seismographs of the same model, but not by several seismographs of different kinds; the shock felt by an experienced observer.

II. Extremely feeble shock: recorded by seismographs of different kinds; felt by a small number of persons at rest.

III. Very feeble shock: felt by several persons at rest; strong enough for the duration or the direction to be appreciable.

IV. Feeble shock: felt by persons in motion; disturbance of movable objects, doors, windows; cracking of ceilings.

V. Shock of moderate intensity: felt generally by everyone; disturbance of furniture and beds, ringing of some bells.

VI. Fairly strong shock: general awakening of those asleep; general ringing of bells, oscillation of chandeliers, stopping of clocks; visible disturbance of trees and shrubs; some startled persons leave their dwellings.

VII. Strong shock: overthrow of movable objects; fall of plaster; ringing of church bells; general panic, without damage to buildings.

VIII. Very strong shock: fall of chimneys, cracks in the walls of buildings.

IX. Extremely strong shock: partial or total destruction of some buildings.

X. Shock of extreme intensity: great disasters, ruins; disturbance of strata; fissures in the earth's crust; rock-falls from mountains.

Results to be expected.—It may be useful, in conclusion, to point out some of the results we may expect to obtain from a systematic study of earthquakes in this country.

The mere indication of the occurrence of a shock felt at a given place on a given day is of service in the compilation of earthquake statistics, and will tend to give completeness to our seismic record. With the help of such a record we can study the laws of the periodicity and geographical distribution of earthquakes. The time is past for drawing up chronological tables of shocks felt over the whole earth; but the importance of making our records complete for a definite area of study is becoming more and more evident.

The accurate determination of the time of occurrence in different places is of the very highest importance. Such observations, if sufficiently numerous, will help us in investigating the position of the area which constitutes the epicentrum; the way in which the vibrations are propagated outwards from the epicentrum; the velocity of the earth-wave, and the laws according to which the velocity varies with the distance from the origin. A knowledge of the time will also determine the question of the coincidence of shocks in distant areas, separated by a region in which the shock is not felt at all, and of other phenomena which may seem to be more or less intimately connected with the earthquake.

By a study of the intensity in the different parts of the disturbed area, we are enabled to draw one or more iso-seismal lines with a fair approach to accuracy. From the form of these lines we can ascertain the approximate position of the epicentrum; and, from the relative distances between consecutive pairs of such lines, we can determine the way in which the intensity decreases as the earth-wave radiates from the origin, and the relations of this decrease with the form and geological structure of the ground.

The chief point to which our researches at present tend is thus the discovery of the position of seismic foci. But our ultimate object is something higher than and beyond all this. With certain exceptions, the slightest earthquake that occurs must indicate the site and mark the epoch of a step in the process of terrestrial evolution. To determine the laws of seismic distribution in space and time would therefore be to discover, in part, the laws that regulate the development of the earth's great surface-features. The study of earthquakes is fascinating enough in itself, but it acquires a loftier significance when viewed in its wider relations; for through it we may press forward to the solution of the great problem of geology—the origin and growth of mountain-chains.

THE HORNED DINOSAURS OF THE UNITED STATES.

IN vol. xxviii. of NATURE (pp. 439 and 515), an account was given by Prof. Moseley of the magnificent skeletons of Iguanodons now mounted in the Brussels Museum of Natural History, which were at that time regarded as among the most remarkable of that extinct group of giant reptiles commonly known as Dinosaurs. Since that date, however, we have been gradually—thanks to the indefatigable labours of the transatlantic palæontologists—acquiring a fuller knowledge of the representatives of this curious group, of which the remains are preserved in such fine condition in the Secondary rocks of the United States Within the last few years, from the writings of Profs. Marsh and Cope—and more especially the excellent figures by which those of the former are illustrated—we have acquired so much information as to the form and structure of the gigantic Jurassic species belonging to the Sauropodous sub-order of the Dinosaurs—such as *Brontosaurus*—that we have begun to regard these extinct creatures as old friends (or should we rather say enemies?) and to flatter ourselves that our knowledge of the whole class is well nigh complete.

Recent discoveries in the topmost Cretaceous or Laramie deposits of North America have, however, brought to light the existence of a group of Dinosaurs, hitherto only very imperfectly known, which are remarkable, not only on

[1] *Arch. des Sc. phys. et nat.*, 3me pèr. t. xi. pp. 148-149; Fouqué, "Les Tremblements de Terre," p. 22 (footnote); *Bull. del Vulc. ital.*, anno iv. (1877), pp. 39-40.

account of their gigantic dimensions, but as being the most bizarre and uncouth-looking forms which palæontology has yet brought to our notice. These are the so-called horned Dinosaurs of the Laramie, in regard to which several important memoirs have been published both by Prof. Cope and Prof. Marsh. There is, however, unfortunately some difference of opinion between these two eminent palæontologists as to the comparatively trivial point of the proper nomenclature to be applied to the various genera; and we must not be supposed to prejudge this question if we adopt the names employed by Prof. Marsh, to whom we are indebted for our illustrations.

As their name implies, one of the most striking features in the organization of these uncouth monsters is the presence of large horn-cores on the skull, as shown in Fig. 1.

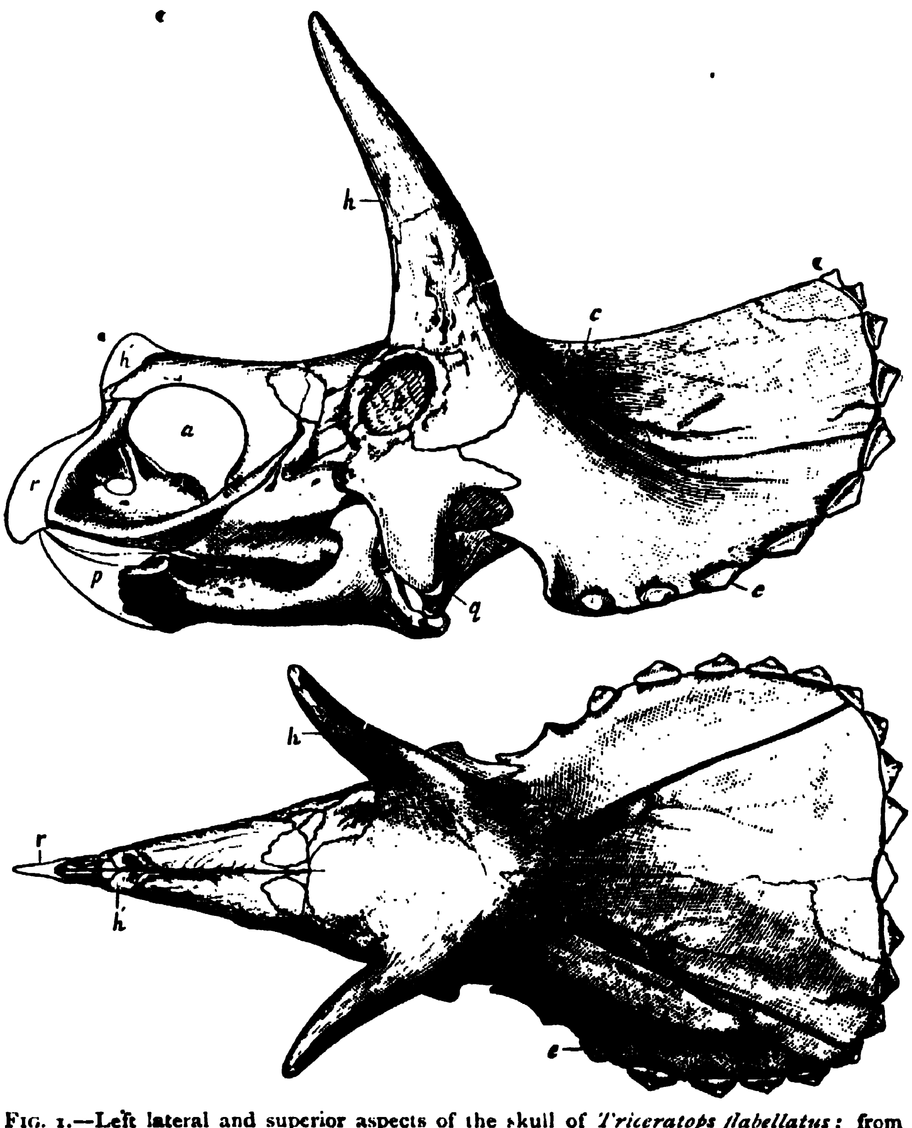


FIG. 1.—Left lateral and superior aspects of the skull of *Triceratops flabellatus*; from the Cretaceous of the United States. 1/30 nat. size. *a*, nostril; *b*, eye; *c*, supratemporal fossa; *e*, epoccipital bone; *h*, frontal, and *h'*, nasal horn-core; *p*, predentary bone; *q*, quadrate bone; *r*, rostral bone. (After Marsh.)

These horn-cores are so like those of the oxen that some detached specimens found lying on the surface of the ground were actually described as belonging to an extinct bison.

The type of skull of which we give a figure belongs to the best known genus, for which Prof. Marsh proposes the name of *Triceratops*. It is remarkable not only for its gigantic size—the length of the figured specimen, which is said to indicate an immature individual, being about six feet—but also for its peculiar armature and structure. An imperfect skull of another species exceeds these dimensions, huge as they are, and is estimated when entire to have had a length of over eight feet. No other known animals, except whales, have a skull making any approach to these dimensions; that of the huge *Brontosaurus* being very small in comparison with the bulk of its owner. The skull of *Triceratops* is remarkable for its wedge-like form when viewed from above, and carries a pair of large horn-cores immediately over the eyes, and a short and single core above the nose. During life it may be inferred with a high degree of probability that these cores were sheathed with horn, like those of oxen, and that they proved equally effective weapons of defence. Equally remarkable is the huge flange-like expansion of the posterior region of the skull, evidently necessary for the attachment of muscles sufficiently powerful to support such a ponderous structure; and it is also peculiar for the presence of an *epoccipital* bone (*e*), which is quite unknown in all other animals. The structure of the teeth is somewhat similar to that obtaining in *Iguanodon*, but each tooth has two distinct roots. As in the latter, the extremity of the lower jaw is devoid of teeth, and likewise has a separate predentary bone at its extremity. The upper jaw is, however, quite peculiar in having a distinct toothless *rostral* bone at the extremity of the premaxillæ. It would thus seem probable that the mouth of these reptiles formed a kind of beak sheathed in horn like that of a tortoise. In young individuals the nasal horn-core is a separate ossification, but in the adult it becomes firmly anchylosed to the underlying bones; so that in this respect we have a precise analogy with the horn-cores of the giraffe. The brain of the creature is very minute—relatively smaller, indeed, than in any known vertebrate; this, however, might have been expected from the size of the brain in other Dinosaurs, since, in the same groups, large animals always have relatively smaller brains than their smaller allies.

Besides mentioning that the limb-bones resemble those of the armed Dinosaurs known as *Stegosaurus*, the only other portion of the skeleton to which we shall allude is the pelvis, of which a representation is given in Fig. 2. In this portion of the skeleton the haunch-bone or ilium (*il*) is remarkable for its great extension both in front of and behind the cavity, or acetabulum (*a*), for the head of the thigh-bone; and also for its horizontal or roof-like expansion, which is in marked contrast to the vertical plate-like form which is assumed by this bone in most other members of the order. With one important exception, the general contour of the pubis and ischium also comes nearest to that found in *Stegosaurus*; this being especially shown in the relation of the former bone to the ilium, and in the shape of the plate which it gives off to form the inner wall of the acetabulum. The remarkable exception is, however, that whereas in *Stegosaurus*, *Iguanodon*, and all other allied forms the pubis gives off a long backwardly projecting process running parallel with the ischium, in the present form there is no trace of any such process.

Mainly from the absence of this postacetabular process of the pubis, Prof. Marsh is disposed to regard the horned Dinosaurs as constituting a distinct primary group of the order; equivalent to those generally known as Sauropoda, Theropoda, and Ornithopoda. The resemblance in the structure of the limb-bones, and in a less degree that of the pelvis, to the loricated forms known as *Stegosaurus*, together with the nature of the dentition, render it, however, far more probable that we should regard these strange reptiles as peculiarly modified forms referable to the sub-order Ornithopoda—the group which includes *Iguanodon* and *Stegosaurus*. In the

course of his description Prof. Marsh remarks that, from the relatively large size of the humerus, the horned Dinosaurs were evidently quadrupedal; and since the presence of a postacetabular process to the pubis is evidently (as exemplified in birds and *Iguanodon*) in some way connected with the bipedal progression,* it may be a fair inference that, owing to the resumption of a quadrupedal progression in the forms under consideration, this process has been lost. We may note that the pubis of *Triceratops* seems undoubtedly to correspond with the pre-acetabular portion of the pubis of *Stegosaurus*, and not with the pubis of *Megalosaurus*, which represents the postacetabular portion of the latter.

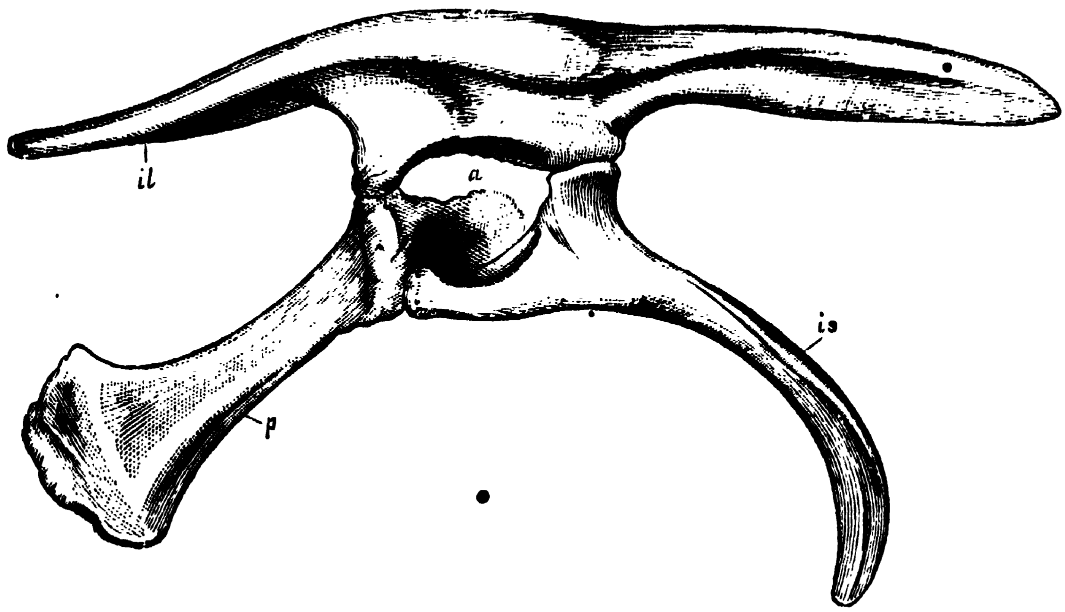

FIG. 2.—Left lateral aspect of the pelvis of *Triceratops flabellatus*. 1/12 nat. size. *a*, acetabulum; *il*, ilium; *p*, pubis; *is*, ischium. (After Marsh.)

The nature of the dentition clearly shows that the horned Dinosaurs of the Laramie were of herbivorous habits, and as it seems impossible that any carnivorous Dinosaurs could have successfully waged war against such giants, we may fairly regard them as the lords of the plain in the distant Cretaceous epoch.

In conclusion we may venture to express the hope that future "finds" will enable the palæontologists of the United States to give us ere long a complete restoration of the skeleton of these mighty denizens of a long-past epoch.

R. L.

THE MEETING OF THE BRITISH ASSOCIATION AT LEEDS.

ON September 3 the sixtieth meeting of the British Association will be opened at Leeds by the President-elect, Sir F. A. Abel, F.R.S. The address, the lectures to the Association, and that to the operative classes will be delivered in the Coliseum, in which upwards of 3400 persons can be well and easily accommodated. By the courtesy of the Mayor and Corporation, the Victoria Hall will be used as the reception-room, and other rooms in the Town Hall will be provided for the various offices. Excellent Section rooms within short distances of the Town Hall have been secured by the kindness of various public and private bodies.

A guide-book, giving an account of the geology, history, places of interest, and manufactures of Leeds and the district, has been prepared, and a list of lodgings and hotel accommodation has been drawn up. Various facilities are offered by the railway companies.

His Worship the Mayor of Leeds proposes to invite the members and associates to a reception and *conversazione* in the Municipal Art Gallery; a *soirée* will be given by the Executive Committee; and an afternoon reception at the Yorkshire College.

From the facility of access due to its central position in the railway system, from the number and variety of its industries, and from the beauty and interest of the country by which it is surrounded, Leeds offers exceptional advantages to visitors, of which many eminent members and foreign men of science have already expressed their intention of availing themselves.

Members interested in applied science and manufactures will be able by the courtesy of employers of labour to acquaint themselves with most of the modern processes by which the wealth of England is being augmented. They will be able to follow the smelting and working of iron until it is converted from clay-ironstone and hematite into tools, engines, pumps, textile machinery, and, in short, into everything which can be made of iron or mild steel. They can inspect the modern improvements in the old industry of Leeds by which wool, shoddy, and mungo are converted or reconverted into woollens or worsteds, and subsequently into clothes. Tanning, boot and shoe making, brewing, and the manufacture of sanitary, fire-resisting, and artistic earthenware employ a large number of hands; while among minor industries may be noted the manufacture of sulphuric acid and other chemicals, of bottles, of paper, of soap, of matches, and of soda-water.

Those interested in geology or scenery will find on the coast and in the diversified strata exposed, much that will instruct and interest them; while, to the historian, the architect, and the archæologist, the minsters, the cathedrals, the abbeys, the churches, the castles, the Roman remains, and the historic houses will furnish many objects worthy of attention.

Excursions may be taken or will be organized, in many cases by invitation, to most of the following places:—Add Church, Kirkstall Abbey, Temple Newsam, Farnley Hall, Harewood House, Boston Spa, Low Moor Iron-works, Pontefract Castle, the Ruskin Museum, Walton Hall and Wakefield, Aldborough, Beverley Minster, Bolton Abbey and Skipton, Castle Howard, Ingleborough, Harrogate, Hemsley and Rivaulx Abbey, Malham Tarn and Gordale Scar, Richmond, Ripon Cathedral and Fountains Abbey, Settle and the Victoria Cave, Scarborough and the coast, Wensleydale, and York.

NOTES.

A MEETING was held at Stonyhurst College, on Tuesday, to consider a proposal for the establishment of some memorial of the late Father Perry. Sir Edward Watkin, M.P., presided, and he was supported by the Bishops of Salford, Shrewsbury, and Mangalore (India), Sir John Lawson, and a large body of Catholic gentry. It was resolved that the memorial should consist of a 16-inch equatorial telescope. A Committee of scientific men was appointed.

THE Town Council of Edinburgh has resolved to renew the invitation to the British Association to meet in Edinburgh in 1892.

THE Australasian Association for the Advancement of Science will hold its third annual meeting at Christchurch, New Zealand. The first general meeting will take place on January 15, 1891, at 8 p.m., when Baron F. von Müller, F.R.S., will resign the chair, and Sir James Hector, F.R.S., President-elect, will deliver an address. The railway authorities of Queensland, New South Wales, Victoria, and South Australia have consented to allow members who are going to attend the Christchurch meeting to obtain return tickets to Sydney or Melbourne at single fares; and various steamship companies have undertaken to convey members to Sydney or Melbourne and back at a reduction of 20 per cent. on the ordinary rates. Application has been made to the New Zealand Shipping Company and to the Shaw, Savill, and Albion Company for passages at reduced rates to members of the British Association visiting New Zealand to attend the meeting, and it is expected that this will be granted. Information may be obtained from Mr. A. Vaughan Jennings, 27 Chancery Lane, the local secretary in London.

THE International Medical Congress, now at work in Berlin, held its first meeting on Monday in the Renz Circus. The Berlin correspondent of the *Times* says it is calculated that no fewer than 4500 members of the medical profession were present, representing every State and city in Europe. Many also came from North and South America. The French delegates, 34 in number, were received with marked cordiality. The medical profession in England was largely represented, among those present being Sir James Paget, Sir Henry Acland, Sir Joseph Lister, Sir John Banks, Sir William Turner, of Edinburgh, Sir William Stokes, of Dublin, Prof. Grainger Stewart, of Edinburgh, Dr. Dick, Director-General of the Naval Medical Department, Mr. Ernest Hart, representing the British Medical Association, Surgeon J. K. Notter, of Netley, representing the War Office, and Dr. Lauder Brunton. The proceedings began with the opening address of the President, Prof. Virchow, who heartily welcomed to Berlin his *confrères* from all parts of the world. The President was followed by Dr. Lassar, Secretary-General of the Congress, who sketched the general plan of the labours of the Congress, and gave some interesting statistics regarding the representation of the countries taking part in it. After Herr von Gossler, Minister of Public Worship, and Herr von Forckenbeck, Burgomaster of Berlin, had welcomed the members in the name of the State and of the town of Berlin, several of the foreign delegates addressed the Congress. Dr. Hamilton, Surgeon-General of the American Army, was the first speaker. He was followed by Sir James Paget, who, on mounting the tribune, was warmly received. A paper on "The Present Position of Antiseptic Surgery," by Sir Joseph Lister, brought the proceedings to a close. At the end of the plenary sitting, the Congress resolved itself into its various Sections, which met in the halls of the Exhibition buildings in Moabit. The proceedings in the Sections on Monday were, for the most part, confined to the election of the various office-bearers. The serious work began on Tuesday.

ON July 22 Messrs. D. C. Worcester and F. S. Bournes left Minneapolis for the Philippine Islands, where they will spend two years in the study of distribution, the collection of birds and corals, and the prosecution of general zoological and botanical work. The expedition was fitted out at a cost of over $10,000, by Mr. L. F. Menage, of Minneapolis, and the collections made by Messrs. Worcester and Bournes will be deposited in the museums of the Minnesota Academy of Sciences at Minneapolis, where also the work upon the collections will be conducted after the return of the explorers.

ON Friday evening an important decision was arrived at in the House of Commons with regard to the revenue to be derived from the new duties on spirits in England. Mr. A. Acland moved that the Council of any county or county borough should receive power to use for the promotion of technical education any part of the share allotted to it, and that the remainder might be used as an educational endowment within the meaning of the Endowed Schools Act, the County Council acting as the governing body of the endowment. To the second part of this amendment—that relating to intermediate education—the Government declined to assent. The first part, however, they accepted. Mr. Mundella, Sir Lyon Playfair, and Sir Henry Roscoe expressed regret that the entire proposal of Mr. Acland was not adopted, but were unanimous in thinking that the decision of the Government, so far as it went, was most satisfactory. Sir Henry Roscoe said he wished to be allowed to say how gratified he was at the acceptance by the Goverment of the first portion of his hon. friend's amendment. To the great centres of industry which had already accepted the Technical Education Act it would be a matter of very great importance. In small places also, especially in the country, the money would be of the very greatest consequence.

DR. NANSEN's expedition to the North Pole will start in the spring of 1892. Captain Sverdrup, who will take the nautical command, is at present on board a fishing-boat in the Polar seas, practising manœuvring among ice. Dr. Nansen wishes that his crew may consist wholly of Norwegian sailors, but will admit some foreigners among the scientific staff.

Science announces that Prof. R. S. Woodward, who was for many years chief geographer of the U.S. Geological Survey, has been appointed assistant in the U.S. Coast and Geodetic Survey. Before his connection with the Geological Survey, Prof. Woodward was assistant astronomer of the U.S. Transit of Venus Commission. He was chairman of the Section of Mathematics and Astronomy of the American Association for the Advancement of Science in 1889, and is well known for his investigations in mathematics, astronomy, and physics.

WE learn from *Science* that records have been received, at the office of the U.S. Coast and Geodetic Survey, of observations made during the last cruise of the *Pensacola*. The stations include the West Coast of Africa, and some islands in the North and South Atlantic. The work was done by an officer of the survey, Assistant E. D. Preston, aided by members of the ship's company. Gravity and magnetic measures were made at St. Paul de Loanda (Angola), Cape of Good Hope, St. Helena, Ascension, Barbadoes, and Bermuda. In addition, magnetic observations alone were made at the Azores (Fayal), Cape Verde Islands (Porto Grande), Sierra Leone (Freetown), Gold Coast (Elmina), and in Angola at Cabiri. The pendulums used in the gravity work were the ones employed in 1883 in Polynesia, and in 1887 at the summit of Haleakala and other stations in the Hawaiian Islands. The computations are now under way at the office in Washington.

PROF. HUXLEY contributed to the *Times* of Tuesday a valuable letter on medical education—the subject with which Dr. Wade had dealt in his Presidential address to the British Medical Association. In this letter Prof. Huxley urges that the scientific training of medical students, and of those who propose to

become medical students, should be much more thorough and exact than it has hitherto generally been. "Those who know what modern medicine is," he says, "are well aware that four years would be but a brief period of study, even if it could be allotted exclusively to the practical branches of the medical science and art. But in the present condition of middle-class education the youth of 17 too commonly enters the medical school, not only devoid of the slightest tincture of scientific knowledge, but, what is worse, so completely habituated to learn only from books or oral teaching that the attempt to learn from things and to get his knowledge at first hand is something new and strange. Thus a large proportion of medical students spend much of their first year in learning how to learn, and when they have done that, in acquiring the preliminary scientific knowledge, with which, under any rational system of education, they would have come provided." Prof. Huxley does not, of course, underrate the importance of a proper literary training for medical students. This, with adequate instruction in science, they might, he thinks, obtain, if our methods of education were improved. The reform for which he especially pleads is that "the time wasted in forcing upon the medical student a sham acquaintance with Latin should be devoted to teaching him the use of his own language and the right enjoyment of its literary wealth, no less than to the study of science."

THE third summer meeting of the University Extension and other students began at Oxford on Friday last. At the opening meeting Prof. Max Müller delivered an address. He defended the method of teaching by means of lectures, but admitted that most lectures were too long, and recommended that they should be limited, as in Germany, to three-quarters of an hour. He also defended the annual gatherings at Oxford against the charge of being mere academical picnics. He showed how well the different classes of lectures had been arranged so as to meet the requirements of different classes of students. He pointed to the large and zealous classes attending these lectures, and to the substantial work done by students who stayed at Oxford for two or three weeks after the public lectures given during the first fortnight were over. Finally, he dwelt on the silent influence which a stay at Oxford must exercise on everyone. "I doubt not," he concluded, "that while teachers and hearers are exploring together in this place the ruins of ancient thought and the labyrinth of modern science, they will feel the silent influence of Oxford, and take to heart the lesson which our University has taught to so many generations of Englishmen, Scotchmen, and Irishmen—respect for what is old and the warmest sympathy for what is new and true."

A CONFERENCE in connection with the University Extension movement was held on Tuesday in the debating hall of the Oxford Union, Mr. Arthur Sedgwick, of Corpus Christi, presiding. There was a large attendance. The subject for discussion was—Is it desirable that local committees should seek to obtain a Treasury grant in aid of the expenses of University Extension teaching? If so, on what conditions is it desirable that the grant should be distributed? The chairman said, speaking as a private individual, and not as a delegate, he most heartily assented to the proposal to ask for State aid for University extension. It seemed to him that there was no test which they could apply in order to see whether an object was worthy of State aid which could not be successfully applied to University extension. In order that the movement might have its proper development it was absolutely necessary that there should be elements of permanence in it. Experience had shown that, at any rate with existing machinery and existing resources, it was extremely difficult to establish this element of permanence. Mr. Macan moved, "That this conference supports the proposal of State aid to University extension, provided that aid could be given without undue State interference." Mr. Mackinder seconded the resolution, which was carried by an overwhelming majority. In the evening a second conference was held in the Examination Schools, the chair being occupied by Mr. J. G. Talbot, M.P. The subjects discussed included University extension teaching in training colleges, village lectures, students' associations, and University extension teaching in connection with free public libraries.

MR. COSMO NEWBERY, the analyst of the Mines Department, Victoria, has been speaking strongly as to the necessity for a central School of Mines in Victoria. He would like that such a school should, if possible, be established in connection with the Melbourne University. If that proved to be impossible, he would be content with the development of the well-known school at Ballarat. Mr. Newbery's views on the subject are vigorously supported by the *Australian Mining Standard*, which thinks that a central school, thoroughly organized, could not fail "to exercise an important influence in the development of mining science in Australasia."

THE University College of Bristol has issued its Calendar for the session 1890–91.

A "*Bibliothèque Darwinienne*" has recently been started in Paris. The series will deal for the most part with sociological subjects. The first volume is by M. P. Combes, and relates to animal civilizations.

ADVANTAGE is being taken of the Eiffel Tower to obtain high pressure through a manometric tube (the height of the tower) containing mercury. M. Cailletet proposes to utilize the enormous pressure—about 400 atmospheres—for his researches on the liquefaction of gases, and interesting results may be looked for.

WE extract from *La Nature* of July 26 the following facts relating to exceptional seasons in past centuries. They have been collected by M. Villard, of Valence, for France especially, and for Europe generally. In 1282 the winter was so mild that cornflowers were sold in Paris in February. New wine was also drunk at Liége on August 24. In 1408 the winter was so severe that nearly all the Paris bridges were carried away by the ice. Ink froze in the pen, although a fire was in the room. [A similar fact is quoted by Dove as occurring at Sebastopol on December 13, 1855.] All the sea between Norway and Denmark was frozen. The summers of 1473 and 1474 were disastrously hot. In the winter of 1544–45 wine was frozen in barrels all over France. It was cut with hatchets and sold by the pound. In 1572–73 nearly all the rivers were frozen. The Rhone was traversed by carriages at various places. In 1585 the winter was very mild; corn was in ear at Easter, but the third week in May was extremely cold.

THE *Annalen der Hydrographie und Maritimen Meteorologie* for July contains an article by Dr. G. Meyer, on the influence of the moon on weather. Although such investigations have hitherto given a negative result, the author thought that with the materials furnished by synoptic charts he might eliminate local influences, and he gives tables extending over a number of years, which seem to show the influence of the moon in lowering the height of the barometer in the months of September to January, at the time of full moon, and in raising it during the first quarter. The Deutsche Seewarte, which communicates the article, points out that a similar result has been independently arrived at by Captain Seemann, one of the assistants of the institution. The same effect or any other is not perceptible in other months.

AN ingenious contrivance has been recently adopted at the Hippodrome in Paris, with a view to producing scenic effects, in the central oval space, without the spectators opposite being seen at the same time. An elliptical screen of fine steel netting is set down in comparative darkness, so as to be about 12 feet in front of the benches. This is painted on the inner side with

a representation of the Place du Vieux Marché at Rouen (the piece being *Jeanne d'Arc*), and, as it is strongly illuminated, at a given moment, from the centre, the light outside being low, a spectator at any point has an excellent view of the scene, while seeing nothing of the crowd beyond.

The additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from West Africa, presented by Miss Florence Schuler; an American Black Bear (*Ursus americanus*) from Canada, presented by Mr. John Sands; a Common Otter (*Lutra vulgaris*) from Ross-shire, presented by the Hon. J. S. Gathorne Hardy, M.P., F.Z.S; two Cape Doves (*Œna capensis*) from South Africa, presented by Miss Grace Debenham; two Imperial Eagles (*Aquila imperialis*) from Spain, presented by Mr. Walter Buck; two Smooth Snakes (*Coronella lævis*) from Hampshire, presented by Mr. E. Penton, F.Z.S; a Hairy Armadillo (*Dasypus villosus*) from La Plata, a Greater Sulphur Crested Cockatoo (*Cacatua galerita*) from Australia, deposited; five Common Peafowls (*Pavo cristatus*), six Ring-necked Pheasants (*Phasianus torquatus*), three Gold Pheasants (*Thaumalea picta*), five Silver Pheasants (*Euplocamus nycthemerus*), seven Californian Quails (*Callipepla californica*), a Vulpine Phalanger (*Phalangista vulpina* ♀) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Objects for the Spectroscope.

Sidereal Time at Greenwich at 10 p.m. on August 7 = 19h. 5m. 29s.

Remarks.

(1) This cluster is thus described in the General Catalogue: "A globular cluster; bright; large; irregularly round; gradually very much compressed in the middle; easily resolved." Dr. Huggins has observed that the spectrum is continuous, with "a suspicion of unusual brightness in the middle," but he apparently made no attempt to determine the position of the brightness. Such a maximum of light in one part of the spectrum is suggestive of radiation phenomena, though of course it is possible that it may be simply a contrast effect due to the presence of dark lines or bands. In any case trustworthy measures may give some clue to the constitution of the stars of which the cluster consists.

(2) The G.C. description of this object is as follows: "Considerably bright; small; irregularly round; easily resolvable." It is thus apparently an undoubted cluster, and it is therefore very remarkable that Dr. Huggins records: "I believe that the spectrum consists of one bright line." If this be confirmed, the object must evidently be a cluster of "nebulous stars," and resolvability can no longer be a criterion for non-nebulosity."

(3) Dunér describes the spectrum of this star as a feebly-developed one of Group II.; only the bands 2, 3, and 7 being seen. As the complete series of bands has been recorded in stars of much smaller magnitude with the same instruments, it is clear that there are decided specific differences. A more detailed examination, with special reference to the presence or absence of bright lines or flutings and dark lines, is suggested.

(4 and 5) These are stars of the solar type and of Group IV. respectively. The usual observations are required in each case.

(6) The spectrum of this star is one of Group VI. The dark bands are strong, but the blue zone is very feeble. Further details should be looked for.

(7) This variable has a spectrum of Group II., and the approaching maximum of August 15 may be utilized for ascertaining whether, in common with other variables of the same group, bright lines appear at or near maximum. The magnitude at maximum appears to vary between 6·6 and 7·7, whilst that at minimum is about 11·5, the period being about 408 days. The line of hydrogen at G is apparently the most easily seen in this class of objects. The bright flutings of carbon should also be carefully observed as the star fades. A. Fowler.

Catalogue of Red Stars.—No. V. of the Cunningham Memoirs of the Royal Irish Academy contains a new edition of Birmingham's "Catalogue of Red Stars," by the Rev. T. E. Espin. The work undertaken by Mr. Espin is (1) the observation of such stars of Mr. Birmingham's Catalogue as seemed to merit special attention; (2) a search for new red stars; (3) the spectroscopic observation of all stars not previously observed with the spectroscope. This comprehensive programme was commenced about four years ago, and much important work has been done under each of the heads. The original catalogue contained ruddy and orange stars in addition to those having a decided red colour, but these are now given in a separate list.

In some remarks on the spectroscopic observations of the stars in the Catalogue, Mr. Espin brings forward "one of the most striking examples of the disagreements among spectroscopic observers," viz. the difference between the spectrum of 152 Schjellerup as observed by Secchi and Dr. Huggins. The former observer remarked that the dark zones coincided with the carbon flutings given by an alcohol flame. Dr. Huggins made the comparison, and, either from imperfect instrumental conditions or a different comparison spectrum, found there was no such coincidence, although later observations, by Vogel, Dunér, and others, have established Secchi's view.

A useful list is given of stars with bright lines in their spectra discovered up to the date of publication, and no one has worked more assiduously in this direction than Mr. Espin himself. After an admirable and extended account of the discovery and the spectra of these stars the following conclusions are arrived at:—

(1) That in stars of type I.*c* (Group I.) where the hydrogen lines and D_3 are bright, the lines vary, and this variation is not simultaneous.

(2) That in stars with type III.*c* one or more of the hydrogen lines may be brilliant and the others invisible, as in Mira, where γ and δ were conspicuous, but there was no trace of ϵ and F.

(3) In the cases of R Andromedæ, R Cygni, and S Cassiopeiæ, the extremely brilliant F line was detected *after* the maximum.

(4) In Vogel's type I.*b*, the hydrogen lines may really be faintly bright, and in one of the stars of this class the existence of other bright lines is proved, and they will hence, probably, be found in others.

It should be remarked that the stars of Group II. which have bright lines in their spectra (*e.g.* Mira Ceta) are classified by Mr. Espin as a new type, III.*c*.

The total number of stars contained in the Catalogue is 1472, of which 766 are given in the red star catalogue, 629 in the list of ruddy stars, and 77 in an addendum. Besides these there are 52 "bright-line" stars. Seven new variables were detected by Mr. Espin during the four years of observation, and he concludes that the work of discovering new red stars in the northern heavens is complete as far as magnitude 8·5. Every spectroscopist appreciates this valuable and important Catalogue, and Mr. Espin is to be congratulated on having been able to complete it in so short a time.

Ancient Eclipses.—In the *Astronomical Journal*, No. 220, Mr. John Stockwell continues his discussion of the secular and long-period inequalities in the moon's motion. The following are the dates of the sixteen eclipses that have been investigated, and some particulars referring to them.

No.	Date.	No.	Date.
1.	A.D. 1140 March 20	9.	B.C. 480 April 19
2.	A.D. 1030 August 30	10.	B.C. 546 October 23
3.	A.D. 364 June 16	11.	B.C. 556 May 19
4.	A.D. 360 August 28	12.	B.C. 584 May 28
5.	A.D. 348 August 29	13.	B.C. 602 May 18
6.	B.C. 309 August 15	14.	B.C. 609 September 30
7.	B.C. 423 March 21	15.	B.C. 762 June 15
8.	B.C. 430 August 3	16.	B.C. 1184 August 28

1. This eclipse is mentioned by Halley, by William of Malmesbury, and in the Saxon Chronicle. It is shown that the line of central eclipse passed over Cambridge.

2. This is the eclipse of Stiklastad, and Mr. Stockwell's computations appear to satisfy the account given by Hansen in vol. ii., p. 388, of his "Darlegung."

3. Observed at Alexandria by Theon.

4. An annular eclipse which occurred before sunrise in any part of Mesopotamia, so that it could not have occasioned the phenomenon mentioned by Ammianus Marcellinus (book xx. chap. 3).

5. This eclipse was total in the eastern parts of Mesopotamia at 9h. 50m., and satisfies the phenomenon described by Ammianus.

6. The eclipse encountered by the fleet of Agathocles while on its voyage from Sicily to Africa.

7. The eclipse described by Thucydides as having occurred during the eighth year of the Peloponnesian War.

8. This eclipse is shown to be identical with that described by Thucydides as having occurred during the first year of the Peloponnesian War, when the darkness was so great that some of the stars were visible.

9. The account given by Aristides ("Scholiast," ed. Frommel, p. 222) of the eclipse which took place while Xerxes was on the march from Sardis to Abydos at the beginning of the Persian War is confirmed by the computations.

10. This is shown to explain the disappearance of the sun described by Xenophon ("Anabasis," Book iii.) as having occurred at Larissa.

11. Contrary to the conclusions of Hansen and Prof. Airy, Mr. Stockwell finds that this eclipse does not satisfy Xenophon's account.

12, 13, and 14. Each of these has been supposed to be Thales's eclipse. Mr. Stockwell finds that both 13 and 14 satisfy equally well the astronomical conditions of the problem, but thinks the former is rather the more probable of the two.

15. The record of this eclipse was discovered on the Assyrian tablets in the British Museum, and the computations show that an eclipse happened at Nineveh at two o'clock in the afternoon on the date given.

16. Homer mentions a singular darkness that occurred during one of the great battles of the last year of the Trojan War ("Iliad," Book xvi.). Mr. Stockwell explains the darkness by means of this total solar eclipse.

Many of the conclusions arrived at with respect to the dates of eclipses differ widely from those generally accepted, and are open to much discussion.

COGGIA'S COMET (*b* 1890).—*Edinburgh Circular* No. 9 contains the following elements and ephemeris, computed by Dr. Berberich, of Berlin, from observations made at Marseilles on July 19, and at Kiel on July 21 and 22. Dr. Berberich finds there must be an error in the comet's place deduced at Marseilles on July 18, the date of discovery. He also points out that the orbit closely resembles that of the comet of A.D. 1580.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual summer meeting of the Institution of Mechanical Engineers was held last week in Sheffield. There could be no more appropriate centre around which either this Institution, or the sister Society, the Iron and Steel Institute, could gather. Sheffield has, however, of late years been somewhat tardy in offering a welcome to visitors. Six years ago it was proposed that the Iron and Steel Institute should hold a session in Hallamshire, but Hallamshire would not open its doors, and the Iron and Steel Institute had to journey to Chester. It is 29 years since the Mechanical Engineers met in Sheffield, and now, when they once more congregate there, they find but a partial welcome. The fact is, the big Sheffield steel makers—the Browns, Firths, Cammells, Jessops, and Vickers—have always pursued an absurd policy of secrecy. There is as much Abracadabra about these Sheffield steel makers as ever was practised by the alchemists of old. One can walk into the other steel works of the country with no more formality than presenting one's card, and see all that is to be seen; but these Sheffield works remain a sealed book. The reason given for this is that "The Foreigner" comes over here and learns too much, imparting no information in return. Unhappily for the cogency of this argument it is just the foreigner that the steel makers must admit. All those firms who do work for foreign Governments must admit foreign Government inspectors. These men come into the works to stay for months or even years. They are experts in the business they are engaged upon. They come and go where they will, ask what questions they will, make analyses, tests, and experiments at will; in short, they obtain a thorough and complete knowledge of everything that goes on. When they return home they would look on two or three hundred a year as an ample income, or a hundred pound note as a handsome consulting fee.

In the face of such facts is it not childish to shut out the necessary engineer, who simply wants to satisfy his scientific curiosity regarding the chief material he uses?

Although the big steel makers had shut their doors on the Sheffield visitors, there were still some things of interest left. Many of the older class of crucible steel makers were willing to explain the whole process of steel production as introduced by Huntsman one hundred years ago, and indeed were able to give practical illustrations of the same. Steel affords as much food for contemplation to the industrial economist as to the physicist and chemist. That the addition of less than one half of one per cent. of carbon should so entirely change the character of the metal is curious enough, although so familiar; but that the making of crucible cast steel should have stood, as it has, through the last century of industrial change and revolution is still more surprising. Watt, Faraday, and Thomson, nay, even Bessemer and Siemens, have lived and laboured without writing a single record on the process. Crucibles are still made by hand, charged by hand, pulled out of the fire by hand, teemed by hand, and in fact the steam-engine is not called into requisition throughout the process. The steel manufacturer makes no chemical analysis to find the grade of his steel. He breaks a piece, and his eye tells him by the fracture the percentage of carbon nearly enough for all practical purposes; *i.e.* as nearly as his neighbour knows, who does the same. And yet if one wants trustworthy steel of the highest grade one has to go to Sheffield for it, and pay the Sheffielder's price. All the science of all the engineers, chemists, and physicists of the last hundred years, allied with the industrial activity engendered by the fierceness of modern competition—even the mingling of science and commercial acumen, as in the persons of Siemens and Bessemer—has failed to unseat the ancient steel trade of Sheffield. No wonder the grimy town remains the stronghold of industrial empiricism, where they fall down and worship with the prophets of the rule of thumb.

But though the crucible steel maker is conservative in his method of working, he proved liberal in showing his work to others, and the members of the Institution had a good opportunity of seeing the way in which the finer kinds of steel they use are produced. The works of Messrs. Seebohm and Dieckstahll, Samuel Osborn and Co., and many others in which crucible steel making is carried on, were open to inspection; but, had not Park Gate come to the rescue, those who were unacquainted with the Bessemer or Siemens processes would have had to go to South Wales, Glasgow, or the north-east, where they could find works open to their inspection quite as well organized as any they missed seeing at Sheffield.

There were eight papers down for reading during the meeting, the sittings being held on the 29th and 30th ult. in the large hall of Firth College. The President of the Institution, Mr. Joseph Tomlinson, presided throughout. The papers on the agenda were as follows:—

"On Steel Rails, considered chemically and mechanically," by C. P. Sandberg, London.

"On Recent Improvements in the Mechanical Engineering of Coal Mines," by Emerson Bainbridge, of Sheffield.

"Description of the Park Gate Iron and Steel Works," by C. J. Stoddart.

"Description of the Sheffield Water Works," by Edward M. Eaton, Engineer.

"Description of the Loomis Process for making Gas Fuel," by R. N. Oakman, Jun., of London.

"On Milling Cutters," by George Addy, of Sheffield.

"On some Different Forms of Gas Furnaces," by Bernard Dawson.

"On the Elihu Thomson Electric Welding Process," by W. C. Fish, of London.

The first five papers only were read, the other three being adjourned until the next meeting.

Steel rails first occupied the attention of members, Mr. Sandberg opening the business part of the meeting by reading his paper. The author attributed the well-known greater durability of the first Bessemer rails made in Sheffield, to the hammered blooms and slow running mills of early days. There is no doubt that hardness is a virtue in railway lines, and hardness may be obtained by work; but it can also be obtained chemically. By the latter means, however, other desirable features may be jeopardized. In the tables showing results of tests, given as an appendix to the paper, this point was strongly brought out, the amount of phosphorus being, in the case of some Russian rails, exceedingly high, in fact dangerously so in the opinion of some of our best authorities. In dealing with the question of silicon, the author gave a seasonable reminder as to the different composition required for steel which was to be used in bridge and ship work, and that intended for rails. This point was taken up in the discussion, Messrs. Windsor Richards, Jeremiah Head, and others speaking on the question of mechanical tests. Tensile tests were generally pronounced as undesirable, being costly, and of little or no use; the falling weight test, and a test for hardness, together with such light as might be thrown by chemical analysis, being considered sufficient. It may be pointed out, however, that there is no well-established means of testing for hardness. Mr. Wicksteed spoke to the point when he referred to the desirability of ascertaining the percentage of elongation, although, as will be seen, this is not a sure guide. This question leads up to another which arose in the discussion. Some of the rail-makers present exclaimed against engineers insisting on steel containing a given percentage of certain alloys. The engineers have nothing to do with chemical analysis, the metallurgists say; it is a subject they know little or nothing about, and yet they lay down the law to the steel makers, whose business it is. Let the engineers be satisfied with results, and leave to those who understand the question the means of attaining these results. This is very good logic as far as it goes, but unfortunately it is not easy to make tests which will definitely settle the question of practical use. One speaker very well said that he looked on the Metropolitan Railway as the best testing machine for rails in the world; and so long as engineers find that a given chemical analysis gives a durable and safe steel rail, they will be justified in asking for that analysis as supplementary to mechanical tests. Speaking on the latter question, the author says in the paper: "As for tensile tests, they tell us very little; for soft rails broke at only 33 tons per square inch, instead of 41 tons for the good rails; while the brittle rails gave almost the same tensile strength as the good rails, and even more elongation and contraction." Could the transverse test under a falling ball have been substituted for these slow and costly tensile tests, it would have shown better the merits of safe or brittle rails. It may be mentioned in passing that the hardness machine of Prof. Turner, of Mason's College, Birmingham, to which Mr. Hadfield made reference, appears to promise well as a means of determining the second desirable feature in steel rails. By the tables to which reference has been made, it was shown that 0·24 per cent. of silicon in steel rails gave the best results. This the author considers the most striking feature in the analysis.

Mechanical engineering in coal-mines, as described in the contribution of Mr. Emerson Bainbridge, next occupied the attention of the meeting. We do not propose giving an abstract of this paper in the present notice; it would be like trying to run the River Thames through a 12-inch main. The author ranged over the whole field of mining engineering; the illustrations, which were shown by aid of the magic lantern, being more than a hundred in number. This paper had evidently cost the author much trouble and time in its preparation, and was one eminently fitted for the consideration of the members of the Institution of Mechanical Engineers. Mr. Bainbridge is well known in the north as a mining engineer of ability—a fact which it is well to emphasize, as his paper was received by some members, not themselves acquainted with its subject, in a very ungracious spirit. It is to be hoped that the proposal which he made to withdraw the paper from publication in the Transactions will not be carried out.

The papers of Messrs. Sandberg and Bainbridge were the only two taken on the first day of the meeting, the sitting being adjourned about one o'clock for the members to visit the various works open to their inspection.

On the members reassembling on the next day, Wednesday, the 30th ult., the first paper taken was that of Mr. C. J. Stoddart. The author is the managing director of the Park Gate Iron and Steel Works, and in his contribution he dealt with the new plant for steel making lately erected there. Should it ever be necessary to put these works into the market, the paper would form an excellent auctioneer's catalogue, it reading more like a document of that nature than a memoir to be put before a meeting of a scientific or technical Society. There were, however, a few passages of historic interest which we reproduce. These works, which are near Rotherham, were founded in 1823, and here many of the iron rails used on the first railways were rolled; amongst some of the later ones were those for the Metropolitan Railway, many of which were case-hardened. Here, also, were rolled a large part of the iron plates used in the construction of the *Great Eastern;* whilst armour plates were first rolled here also. The latter were presumably for the *Warrior*, as she was our first armour-clad ship, and they were very different from the compound steel and iron plates now so elaborately prepared, being, it will be remembered, no more than 4½ to 5 inches thick. Park Gate has, however, had to abandon these early methods of iron working, and, advancing with the times, has laid down within the last two years a costly steel plant, the outline particulars of which are duly set forth in Mr. Stoddart's catalogue. We are not, however, disposed to quarrel with the author of the paper for not going more fully into particulars, as he was liberal enough, in his capacity as managing director, to invite the meeting to make an excursion to his works on the day following the reading of his paper. The members were therefore enabled to see for themselves the five blast furnaces, plate and sheet mills, bar mills and their appurtenances, four 25-ton Siemens furnaces, cogging mills, slab rolls, billet mills, and plate mills duly set forth in the author's list of plant. The capacity of the steel works is from seven to eight hundred tons of steel and from four to five hundred tons of plates per week.

Mr. Oakman's paper on the Loomis process of making gas fuel was next brought before the meeting. The apparatus in which Loomis gas is made consists mainly of a generator and steam boiler. The generator is not novel in principle, the air being drawn through the charging door in the top, whilst an exhauster is used to set it in motion. The result is producer gas, which is superheated and then led through the boiler to produce steam, finally passing to the gas-holders. This part of the process is carried on for about five or six minutes, after which the admission of air is suspended, and the steam which has been generated is carried through the incandescent fuel, having been previously superheated in the superheater. The second operation produces, of course, water-gas, which, however, has one great advantage over ordinary water-gas, inasmuch as it possesses a strong and characteristic odour. This proceeds from the hydrocarbons taken up from the fuel, a bituminous coal being used. The apparatus has been applied with success in Sheffield, notably by the big steel house of T. Firth and Sons. A representative of that firm stated during the discussion that a saving of at least 50 per cent. in the cost of fuel in the manufacture of crucible steel was made by using Loomis gas, as compared with the old method of melting by coke—a statement which we have no difficulty in accepting when it is remembered how extremely wasteful is the present usual method of firing.

The discussion which followed the reading of the paper soon fell into the familiar groove which seems to have become stereotyped for use whenever the question of gas fuel comes to the fore. Mr. John Head and Sir Lowthian Bell both spoke. The former naturally soon brought the subject round to the Siemens furnace; upon the merits of which he was speaking

—especially in the matter of cheapness—when he was stopped by the President. The practice Mr. Head follows at meetings of the scientific and technical Societies is not tending to enhance the respect felt for the once honoured name of Siemens. Sir Lowthian Bell said what he said in Paris last year over again. The position he takes up—that no more heat can be got from a pound of fuel than Nature put in it—is perfectly sound, but there is no need to repeat the truism at such great length and so often.

The Sheffield Water Works was the subject of the last paper read at the meeting.

On the whole, it cannot be doubted that the meeting of the Mechanical Engineers at Sheffield was below the average, and badly managed. If Mr. Eaton's paper on the water-works had been taken as read, and Mr. Addy's contribution on milling cutters had been brought forward, the meeting might have done something to redeem its character as a representative assemblage of Mechanical Engineers. The Catalogue of the Park Gate Iron and Steel Works might also have been taken as read. Both the latter and the water-works paper were acceptable as guides to the respective excursions, but that was no reason why members should be required to sit and listen whilst Mr. Bache read through them at a speed which rendered it quite impossible to follow.

We have not space to refer to the visits to works in Sheffield open to visitors, and indeed there was not much of exceptional interest. Exception must be made, however, to a loom for weaving horse-hair cloth, which was seen at the works of Laycock and Sons. The wonderful ingenuity displayed by designers of textile machinery appears here to have reached its culminating point. Horse-hair has several undesirable features from a textile point of view. The filaments are generally no longer than 3 or 4 feet; though exceptional hairs have been known as long as 6 feet, we believe. The thickness differs considerably at each end; the material is very elastic, and it is so hard that it will speedily wear away the hardest steel over which it may be dragged. In order to overcome these difficulties, the designer of this loom, Mr. W. S. Laycock, has introduced a shuttle with jaws that take hold of each hair as it is presented, and a device which is known as the selector. The latter is a hand—for we can call it nothing less—which picks up one hair, and only one, to present to the jaws of the shuttle. It has to let go at the very instant the shuttle takes hold, otherwise the hair would be dragged through its fingers, which would soon be worn away. Sometimes, however, the fingers fail to grasp this single hair; it must be remembered if it were to take two hairs the cloth would be spoiled. It then makes a second try, and, if the second fail, yet a third. Supposing the third attempt also prove unsuccessful, there being no time to make a fourth, the selector promptly stops the weft motion, so that no change takes place whilst the shuttle is making its traverse without a hair to form the weft. Theophrastus Such, after a visit to a textile factory, had a nightmare, in which mechanism usurped the place of humanity, and became the inexorable master of mankind. The conceit is worked out with much skill, and appears quite plausible when viewed in the light of mechanism which not only performs the most delicate operations, but knows when it misses, tries again as long as trying is of avail, and, if it fail at last, takes steps to prevent mischief following.

ON THE ORIGIN OF THE DEEP TROUGHS OF THE OCEANIC DEPRESSION: ARE ANY OF VOLCANIC ORIGIN?[1]

THE consideration of the question with regard to the origin of the ocean's deep troughs requires, as the first step, a general review of oceanic topography; for according to recent bathymetric investigations, the deep troughs are part of the system of topography, and its grander part. We need, for this purpose, an accurate map of the depths and heights through all the great area. Such a map will ultimately be made through the combined services of the Hydrographic Departments of the civilized nations. At the present time the lines of soundings over the oceans, especially over the Pacific and Indian, are few, and only some general conclusions are attainable. It is to be noticed that the system of features of the oceanic area are involved in the more general terrestrial system; but since the former comprises nearly three-fourths of the surface of the sphere, it is not a subordinate part in that system.

With reference to this discussion of the subject I have prepared the accompanying bathymetric map.

[1] This paper is accompanied in the *American Journal of Science* from which it is reprinted, by a bathymetric map.

I. THE BATHYMETRIC MAP, AND THE GENERAL FEATURES OF THE OCEANIC DEPRESSION DISPLAYED BY IT.

1. *The Map.*—In the preparation of the bathymetric map I have used the recent charts of the Hydrographic Departments of the United States and Great Britain,[1] which contain all depths to date, and the lists of new soundings published in German and other geographical journals. In order that the facts on which the bathymetric lines are based may be before the reader a large part of the depths are given, but in an abbreviated form, 100 fathoms being made the unit: 25 signifying 2500 fathoms or nearly (between 2460 and 2550); 2·3, about 230 fathoms, ·4, about 40 fathoms. Only for some deep points is the depth given in full. The addition of a plus sign (+) signifies no bottom reached by the sounding.[2]

In the plotting of oceanic bathymetric lines from the few lines of soundings that have been made, the doubts which constantly rise have to be settled largely by a reference to the general features of the ocean, and here wide differences in judgment may exist in the use of the same facts; but through the depths stated on the map, the reader has the means of judging for himself. In the case of an island the lines about it may often have their courses determined by those of adjoining groups, or by its own trend; but in very many cases new soundings are needed for a satisfactory conclusion.

Some divergences on the map from other published bathymetric maps require a word of explanation. The northern half of the North Pacific is made, on other deep-sea maps, part of a great 3000-fathom area (between 3000 and 4000) stretching from the long and deep trough near Japan far enough eastward to include the soundings of 3000 fathoms and over in mid-ocean along the 35th parallel. It has seemed more reasonable, in view of present knowledge from soundings, to confine the deep-sea area off Japan to the border-region of the ocean, near the Kurile and Aleutian Islands, and leave the area in mid-ocean to be enlarged as more soundings shall be obtained. Again, in the South Pacific, west of Patagonia, the area of relatively shallow soundings (under 2000 fathoms) extending out from the coast, is on other maps bent southward at its outer western limit so as to include the area of similar soundings on the parallels of 40° and 50°, between 112° and 122° W. The prevailing trends of the ocean are opposed to such a bend, and more soundings are thought to be necessary before adopting it.

It may be added here that in the Antarctic Atlantic, about the parallel of 66½° S. and the meridian of 13½° W., a large area of 3000 and 4000 fathoms has been located. It was based, as I have learned from the Hydrographic Department of the British Admiralty, on a sounding in 1842 by Captain Ross, R.N., in which the lead ran out 4000 fathoms without finding bottom. The sounding was, therefore, made before the means available were "sufficient to insure the accuracy of such deep casts."[3]

2. *The Feature-lines of the Oceanic and Bordering Lands.*—The courses of island-ranges and coast-lines have a bearing on the question relating to the courses of the deep-sea troughs, and

[1] I am indebted to the Hydrographic Departments of Great Britain as well as the United States for copies of these charts.

[2] On the map the bathymetric lines for 1000, 2000, 3000, and 4000 fathoms, besides being distinguished in the usual way by number of dots, have been made to differ in breadth of line, the deeper being made quite heavy in order to exhibit plainly the positions of the areas without the use of colours. The line for 100 fathoms is, as usual, a simple dotted line. As the bathymetric map herewith published is necessarily small, and none of the ordinary maps of the oceans give either deep-sea soundings or a correct idea of the trends of the oceanic ranges of islands, I state here that the charts of the U.S. Hydrographic Department for the Atlantic, Pacific, Indian, and Arctic Oceans may be purchased of dealers in charts in the larger sea-board cities for 50 cents a sheet and less according to size. (There are several large charts to each ocean.) One of the firms selling them in New York City is that of T. S. and J. D. Negus, 140 Water Street. The British Admiralty have published a map of the Pacific with its soundings on a single sheet, and for the Atlantic and Indian Oceans with part of the Pacific, besides charts of the Antarctic and Arctic seas. The occasional Bulletins from the Hydrographic Department and *Petermann's Mitteilungen* contain nearly all the new data issued for the perfecting of such a chart.

[3] The communication received from the Admiralty Office adds that "Some of Ross's soundings up to 2660 fathoms have been proved correct, and hence the sounding in 68° S., referred to, has been retained on our charts until disproved." "Another sounding obtained by Ross in the Atlantic has had strong doubts thrown upon it by a sounding of 3000 fathoms obtained not very far from its position." See the accompanying map, near latitude 74° S.

therefore, by way of introduction, they are here briefly reviewed.[1] The system of trends in feature-lines takes new significance from a bathymetric map, for the courses are no longer mere trends of islands or emerged mountain peaks; they are the trends of the great mountain ranges themselves; and, in the Pacific, these mountain courses are those of half a hemisphere. Some of the deductions from such a map are briefly as follows:—

(1) Over the Pacific area there are *no* prominent north-and-south, or meridional, courses in its ranges, and none over the Atlantic, except the axial range of relatively shallow water in the South Atlantic. And to this statement it may pertinently be added that there are none in the great ranges of Asia and Europe, excepting the Urals; none in North America; none in South America, excepting a part of those on its west side.

(2) The ranges in the Pacific Ocean have a mean trend of not far from north-west-by-west, which is the course very nearly of the longer diameter of the ocean. One *transverse* range crosses the middle South Pacific—the New Zealand—commencing to the south in New Zealand and the islands south of it, with the course N. 35° E., and continuing through the Kermadec Islands and the Tonga group, the latter trending about N. 22° E., and this is the nearest to north and south in the ocean, except toward its western border.

(3) The oceanic ranges are rarely straight, but, instead, change gradually in trend through a large curve or a series of curves. For example, the chain of the central Pacific becomes, to the westward, north-north-west; and the Aleutian range and others off the Asiatic coast make a series of consecutive curves. Curves are the rule rather than the exception. Moreover, the intersections of crossing ranges, curved or not, are in general nearly rectangular.

(4) Approximate parallelisms exist between the distant ranges or feature-lines; as (1) between the trend of the New Zealand range and that of the east coast of North America; and also that of South America (which is continued across the ocean to Scandinavia); also (2) between the trend of the foot of the New Zealand boot with the Louisiade group and New Guinea farther west, and the mean trend of the islands of the central Pacific both south and north of the equator, and also that of the north shore of South America. These are a few examples out of many to be observed on the map.

(5) The relatively shallow-water area which stretches across the North Atlantic from Scandinavia to Greenland—the Scandinavian plateau, as it may well be called—is continued from these high latitude seas south-westward, in the direction of the axis of the North Atlantic (or parallel nearly to the coast of eastern North America and the opposite coast of Africa), and becomes the "Dolphin Shoal."

It may be a correlate fact in the earth's system of features that a Patagonian plateau stretches out from the Patagonia coast, or from high southern latitudes, in the direction of the longer axis of the Pacific, and embraces the Paumotu and other archipelagos beyond.[2]

The above review of the earth's physiognomy, if accompanied by a survey of the map, may suffice for the main purpose here in view: to illustrate the general truths—that system in the feature-lines is a fact; that the system is world-wide in its scope; and—since these feature-lines have been successively developed with the progress of geological history—that the system had its foundation in the beginning of the earth's genesis and was developed to full completion with its growth.

II. FACTS BEARING ON THE ORIGIN OF THE DEEP-SEA TROUGHS.

In treating of this subject, the facts from the vicinity of volcanic lands that favour a volcanic origin are *first* mentioned; *secondly*, those from similar regions that are not favourable to such an origin; *thirdly*, facts from other regions bearing on the question

A. *Facts apparently favouring a Volcanic Origin.*

1. The Pacific soundings have made known the existence of two deep-sea depressions, if not a continuous trough, *within forty miles of the Hawaiian Islands*; one situated to the north-east of Oahu, or, north of Molokai, with a depth of 3023 fathoms, or 18,069 feet, and the other east of the east point of Hawaii, 2875 fathoms, or within 750 feet of 18,000 feet. Again, 450 miles north-east of Oahu, there is a trough in the ocean's bottom, over 800 miles long, which runs nearly parallel with the group and has a depth of 3000 to 3540 fathoms; and, as far south, another similar trough of probably greater length has afforded soundings of 3000 to 3100 fathoms. The depths about the more western part of the Hawaiian chain of islands have not yet been ascertained, and hence the limits of the deep areas are not known. Such depths, so close to a line of great volcanic mountains, the loftiest of the mountains not yet extinct, appear as if they might have resulted from a subsidence consequent on the volcanic action.

The subsidence might have taken place (1) either from underminings—which the amount of matter thrown out and now constituting the mountain chain, with its peaks of 20,000 to 30,000 feet above the sea-bottom, shows may be large; or (2) from the gravitational pressure in the earth's crust, about a volcanic region which speculation makes a source of the ascensive force and of the upward rising of the lavas, the subsiding crust following down the liquid surface beneath. In either case the mass of ejected material might be a measure more or less perfectly of the maximum amount of subsidence.

2. In the western part of the North Pacific, at the south end of the volcanic group of the Ladrones off the largest island of the group, Guam, the *Challenger* found a depth of 4475 fathoms, one of the two deepest spots yet known in the Pacific. The situation with reference to the group is like that off the east end of the Hawaiian group.

3. East of Japan and the Kuriles, a region of ranges of volcanoes, there is the longest and deepest trough of the ocean, the length 1800 miles, the depths 4000 to 4650 fathoms; and farther north-east, south of one of the Aleutian Islands, a depth of 4000 fathoms occurs again; and depths of 3100 to 3664 fathoms also still farther east. It is probable that the 4000-line trough continues from the Kurile to this deep spot off the Aleutian volcanic range; and if so, the length of the trough is over 2500 miles. The map is made to suggest its extension still farther eastward; but among the very few soundings made, none below 3664 fathoms have yet been obtained off the more eastern Aleutians.

Other similar facts may be found on the map; and still others may exist which are not now manifest owing to the sinking of oceanic areas and islands. But no cases can be pointed to which are more decisively in favour of volcanic origin.

B. *Facts from the Vicinity of Volcanic Regions apparently not referable to a Volcanic Origin.*

The ocean off the western border of North and South America affords striking examples of the absence of deep troughs from the vicinity of regions eminently volcanic. The South American volcanoes are many and lofty; and still the ocean adjoining is mostly between 2000 and 2700 fathoms in depth; and just south of Valparaiso, it shallows to 1325 fathoms. The only exception yet observed is that of a short trough of 3000 to 3368 fathoms close by the Peruvian shore. It may, however, prove to be a long trough, although certainly stopping short of Valparaiso. The waters, however of the Pacific border of America deepen abruptly compared with those of the Atlantic border; and the significance of this fact deserves consideration.

The facts off Central America are more remarkable than those off the coast to the south. The volcanoes are quite near to the Pacific coast, and still the depths are between 1500 and 2500 fathoms.

The condition is the same off the west coast of North America. Of the two areas of 3000 and over, nearest to the east coast of the North Pacific, one is 600 miles distant in the latitude of San Francisco, and the other is within 10° of the equator and 20° of the coast; both too far away to be a consequence of volcanic action in California, Mexico, or Central America.

[1] This subject of the system in the earth's feature-lines is presented at length, with a map, in my Expedition Geological Report, pp. 11–23 and 414–424; and also more briefly in the *American Journal of Science*, II. ii. 381, 1846.

[2] As parallelisms may have importance that is not now apparent, I draw attention to one between the Mediterranean Sea that divides Europe from Africa, and the West India (or West Mediterranean) sea that divides North from South America. Both have an *eastern*, *middle*, and *western* deep basin. Their depths (see map) in the East Mediterranean, are 2170, 2040, and 1585 fathoms; in the West Mediterranean (the three being the Caribbean, the West Caribbean or Cuban, and the Gulf of Mexico), 2804, 3428, and 2080 fathoms. Further, in each Mediterranean Sea, a shallow-water plateau extends from a prominent point on the south side, northward, to islands between the eastern and middle of the deep basins; one from the north-east angle of Tunis to Sicily, the other from the north-east angle of Honduras to Jamaica and Haiti, the two about the same in range of depth of water. And this last parallelism has its parallels through geological history, even to the Quaternary, when the great Mammals made migrations to the islands in each *from the continent to the south*.

In the North Atlantic the European side has its volcanoes, and has had them since the Silurian era, and yet the non-volcanic North American side of the ocean has far the larger areas of deep water and much greater mean depth. The Azores or Western Islands, which are all volcanic, have depths around them of only 1000 to 2000 fathoms, and no local troughs. Iceland, the land of Hecla, is in still shallower waters, with no evidence of local depressions off its shores. The Canaries are volcanic, but no deep trough is near them.

C. *Facts from Regions not Volcanic which are unfavourable to the idea of a Volcanic Origin.*

1. In the North Pacific, near its centre, the area of 3000 or more fathoms about 35° N.; the two similar but smaller areas toward its eastern border; the areas north of the Carolines in the western part of the ocean; the broad equatorial area about the Phœnix group; the area in the South Pacific in 170° W., east of Chatham Island, and another just south of Australia, are all so situated that no reason is apparent for referring them to a volcanic origin. Some of the areas are in the coral island latitudes, and the supposed volcanic basis of coral islands makes a volcanic origin possible, but their probable size and position appears to favour the idea of origin through some more fundamental cause. The area in the South Pacific, east of Chatham Island, is 450 miles distant from the land. The border of southern Australia, abreast of the deep-sea trough, has no known volcano.

2. *In the Atlantic, away from the West Indies.*—The 3000-fathom areas of the North and South Atlantic—that is, the three in the North Atlantic, the two in the South Atlantic, and the two equatorial, one near the coast of Guinea and the other near that of South America—occupy positions that suggest no relation to volcanic conditions. The Cape Verdes, north of the equator, are partly encircled by one of the deep areas, somewhat like the eastern end of the Hawaiian group; but this bathymetric area appears to be too large to owe its origin directly to volcanic work in the group. The coast of Guinea near the 3000-fathom area has nothing volcanic about it, and the opposite coast of South America, near another, is free from volcanoes.

The only facts in the Atlantic that suggest a volcanic origin are the depression of 2445 fathoms within 40 miles of the west side of the volcanic Cape Verde archipelago, and that of 2060 fathoms within 20 miles of Ascension Island; and a connection is possible.

3. *In and near the West Indies.*—The most remarkable of the depths of the Atlantic area are situated in and near the region of the West Indies, as is well illustrated and discussed by Mr. Alexander Agassiz in his instructive work on the "Three Cruises of the *Blake*." The deepest trough of the ocean, 4561 fathoms, occurs within seventy miles of Porto Rico; and yet this island has no great volcanic mountain, though having basaltic rocks. By the north side of the Bahama belt of coral reefs and islands, for 600 miles, as Mr. Agassiz well illustrates, the depth becomes 2700 to 3000 fathoms within twenty miles of the coast-line, and at one point 2990 within twelve miles, a pitch-down of 1 : 3·5; and nothing suggests a volcanic cause for the abrupt descent. Cuba and Hayti are not volcanic, and look as if they were an extension of Florida, so that no grounds exist for assuming that the Bahamas rest on volcanic summits.

One of the strangest of 3000-fathom troughs is that which commences off the south shore of Eastern Cuba, having there a depth of 3000 to 3180 fathoms. It is within 20 miles of this non-volcanic shore, and nearly three times this distance from Jamaica. No sufficient reason appears at present for pronouncing its origin volcanic. It is continued in a west-by-south direction to a point beyond the meridian of 85° W., or over 700 miles, making it a very long trough, and the depths vary from 2700 to 3428 fathoms. The depression extends on into the Gulf of Honduras, carrying a depth of 2000 fathoms far toward its head, and in a small indentation of the coast it stops; for nothing of it appears in the outline of the Pacific coast or the depths off it, and nothing in the range of volcanic mountains on the coast. Against the three deepest parts of the trough there are, *first*, the Grand Cayman Reef, 20 miles north of a spot 3428 fathoms deep; *second*, banks in 13 and 15 fathoms within 15 miles of a depth of 2982 fathoms; and *third*, Swan Island Reef, 15 miles south of a depth of 3010 fathoms; the first of the three indicating a slope to the bottom of 1 : 5, and the last of 1 : 4·4. Why these greatest depths in the trough, so abrupt in depression, should be on one side of shoals or emerged coral reefs, it is not easy to explain; and the more so that the part of the trough south of Cuba has nothing volcanic near by in the adjoining mountain range, and the fact also that the westernmost end of the trough extends on for 175 miles, and there has a depth of 3048 fathoms, with 2000 fathoms either side and no coral reefs.

D. *Arrangement of the Deep-sea Troughs in the two halves of the Oceans, pointing to some other than a Volcanic Origin.*

The *western* half of the Atlantic and Pacific oceans contains much the larger part of the 3000-fathom areas and all the depths over 4000 fathoms. In the North Atlantic the areas of 3000 and over in the western half, or off the United States, are very large; and the bathymetric line of 2500 fathoms extends westward nearly to the 1000-fathom line. This important feature can be appreciated for both oceans from a look at the map without special explanations.

As a partial consequence of this arrangement, the Pacific, viewed as a whole, may be said to have a westward slope in its bottom, or from the South American coast toward Japan. This westward slope of the bottom exists even in the area between New Zealand and Australia—the ocean in this area being shallow for a long distance out on the east side and deepening to 2500–2700 fathoms close to that non-volcanic land, New South Wales, in eastern Australia. In the Atlantic, the slope is in the direction of its north-east–south-west axis, either side of the Dolphin Shoal, but especially the western side, rather than from east to west, it commencing in the Scandinavian plateau and ending in the great depths adjoining the West Indies.

Owing to the system in the Atlantic topography, the Dolphin Shoal—the site of the *Atlantis* of ancient and modern fable—is really an appendage to the eastern continent, that is to Europe, and is shut off by wide abyssal seas from the lands to the west that have been supposed to need its gravel for rock-making.

But the view that the west half of an oceanic basin is always the deepest becomes checked by finding in the Indian Ocean that the only areas that are 3000 fathoms deep or over are in the *eastern* part of the ocean and off the north-west coast of Australia, and near western Java and Sumatra. The greatest depths in its western half or toward Africa, are 2400 to 2600 fathoms.[1]

III. CONCLUSIONS.

1. The facts reviewed lead far away from the idea that volcanic action has been predominant in determining the position of the deep-sea troughs. It has probably occasioned some deep depressions within a score or two of miles of the centre of activity, but beyond this the great depths have probably had some other origin.

2. It is further evident that the deep-sea troughs are not a result of superficial causes of trough-making. Erosion over the ocean's bottom cannot excavate isolated troughs. The coldest water of the ocean stands in the deep holes or troughs instead of running, as the reader of Agassiz's volume has learned.

The superficial operation of weighting the earth's crust with sediment, or with coral or other organic-made limestone, and filling the depressions as fast as made, much appealed to in explanations of subsidence, has not produced the troughs; for filled depressions are not the kind under consideration. Moreover, the areas are out of the reach of continental sediments and too large and deep to come within the range of possibilities of organic sedimentation or accumulation. The existence of the troughs is sufficient proof of this. The deep troughs of the West Indian and adjoining seas are in a region of abundant pelagic and sea-border life, and yet the marvellous depths exist. And the depths of the open oceans are no less without explanation. Those close by the Bahamas, extending down to 16,000 and 18,000 feet, are evidence of great subsidence from some cause; and the coral reefs for some reason have manifestly kept themselves at the surface in spite of it.[2]

3. If superficially acting causes are insufficient, we are led to look deeper, to the sources of the earth's energies, or its interior

[1] In the Arctic seas, going north from the Scandinavian plateau, the water deepens north of the latitude of Iceland, between Greenland and Spitzbergen, to 2000 fathoms, and farther north to 2650 fathoms, in the latitude nearly of Greenwich; and it is probable that the 2000-fathom area extends over the region of the North Pole. The continents of Europe (with Asia probably) and North America are proved by the shallow soundings over the adjoining Arctic seas and the islands or emerged land, to extend to about 81½° N., which is about 450 miles from the Pole.

[2] The migrations from South America alluded to in note [2] on page 358, proving an elevation of 2000 feet, to make it possible, prove also that a large part of the West India seas *afterward* suffered subsidence in the Quaternary. How far the Bahama and Florida region participated in the subsidence is not known. That it did not participate in it has not been proved.

agencies of development, to which the comprehensive system in its structure and physiognomy points. Whatever there is of system in the greater feature-lines, whether marked in troughs or in mountain chains, or island ranges, must come primarily from systematic work within. The work may have been manifested in long lines of flexures or fractures as steps in the process, but the conditions which gave directions to the lines left them subject to local causes of variation, and between the two agencies, the resulting physiognomy has been evolved.

We have from the Pacific area one observation of a volcanic nature bearing on the comprehensiveness of the system of feature lines in the oceans, and although I have already referred to it, I here reproduce the facts for use in this place.

If the ranges of volcanic islands were, in their origin, lines of fissures as a result of comprehensive movements, the lines should continue to be the courses of planes of weakness in the earth's crust. The New Zealand line, including the Kermadec Islands and the Tongan group, has been pointed to as one of these lines, and one of great prominence, since it is the chief north-eastward range of the broad Pacific, and nearly axial to the ocean. The series of volcanoes along the axis of New Zealand is in the same line. It was noticed, at the Tarawera eruption of 1883, that *four or five days after* the outbreak, and three after it had subsided, White Island, in the Bay of Plenty, at the north end of the New Zealand series, became unusually active; and *two months later* there was a violent eruption in the Tonga group, on the Island of Niuafou. The close relation in time of the latter to the New Zealand eruption is referred to by Mr. C. Trotter, in NATURE of December 7, 1886.[1] May it not be that these disturbances were due to a slight shifting or movement along a series of old planes of fractures, taking place successively from south to north; and, hence, that even now changes of level may take place through the same comprehensive cause that determined the existence of the earth's feature lines? Owing to the long distance of the Tonga group from New Zealand an affirmative reply to the question cannot be positively made. But there is probability enough to give great interest to this branch of geological enquiry. JAMES D. DANA.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 28.—M. Hermite in the chair.—Aquatic locomotion studied by photo-chronography, by M. Marey. The author has made similar investigations on animal locomotion to those of Mr. Muybridge, but with different apparatus. A single camera, the sensitive plate of which takes the form of an endless band moving past the focus of the lens, has been used in the investigations, and appears to possess many advantages over the multiple camera system. The contractions and dilatations of the body of the medusa, the undulations of the lateral fins of the ray, and the rapid movements of the dorsal fin of the *Hippocampus* (sea-horse), have all been analyzed, and in the zoëtrope the successive photographs appear to have reproduced the motions to perfection.—Observations, orbit, and ephemeris of the comet discovered by M. Coggia (*b* 1890) at Marseilles Observatory, by M. Stephan.—On the observation of the annular eclipse of the sun of June 17, by M. A. de la Baume Pluvinel. A detailed description of the instruments employed by the author for his observations in Canea (Island of Crete) is given. As previously noted (NATURE, July 10), the results give further support to the view that the oxygen absorption bands in the solar spectrum are of telluric origin.—Observations of the minor planet recently discovered by M. Charlois (294), made with the *coudé* equatorial and the Foucault telescope at Algiers Observatory, by MM. Rambaud and Sy. Some observations of position and comparison stars are given.—Observations of Coggia's comet, made with the great equatorial of Bordeaux Observatory, by MM. Picart and Courty.—Observations of the same comet made at Paris Observatory, by Mdlle. D. Klumpke.—On a new method of exposition of the theory of theta functions, and on an elementary theorem relative to hyperelliptic functions of the first dimension, by M. F. Caspary. It is shown that the fifteen hyperelliptic functions of the first dimension are proportional to the fifteen elements of an orthogonal system.—Earthquakes in Madagascar, by M. R. P. Colin, Director of the Antananarivo Observatory. The five earth-tremors observed this year appear to have had an influence on the azimuth error of the transit instrument.—On the water of crystallization of neutral sulphate of alumina; analysis of a natural product, by M. P. Marguerite-Delacharlonny. The analysis of two samples of definitely crystallized natural sulphate of alumina from Bolivia supports the author's previous conclusion that its formula should be written with sixteen instead of eighteen molecules of water of crystallization.—On the optical rotatory power of camphor in solution in various oils, by M. P. Chabot. The author finds that the rotation produced by the solutions is sensibly proportional to their strengths, and that, after allowing for the slight rotation due to the oil, the calculated molecular rotatory power of camphor is practically constant.—On the malonates of lithia and on the malonate of silver, by M. G. Massol. Some experiments on the heats of formation are given.—Researches on the optical dispersion of organic compounds; fatty acids, by MM. Ph. Barbier and L. Roux. The authors have examined the normal fatty acids from formic to pelargonic as well as isobutyric and isovaleric acids, and find that the specific dispersive powers increase with the molecular complexity, and that those of isomeric acids are practically equal, though the normal acids have slightly the higher value.—On the presence of furfural in commercial alcohols, by M. L. Lindet.—Contribution to the study of artificial musk, by M. Albert Baur.—Mode of action of bacterial secretions on the vasomotor nervous system; connection between these phenomena and diapedesis, by MM. A. Charrin and E. Gley.—Does hæmoglobin exist in the blood as a homogeneous substance?, by M. Christian Bohr.—On the identity of structure of the central nervous system of Pelecypoda and other Mollusca, by M. Paul Pelseneer.—On the bathymetric distribution of the deep-sea Brachiopods collected in the *Travailleur* and *Talisman* expeditions, by MM. P. Fischer and D. P. Œhlert.—On the position in the plant of the compounds which produce the sulphuretted essential oils of the Cruciferæ, by M. Léon Guignard.

THURSDAY, AUGUST 14, 1890.

THE INCOME-TAX AND THE PROMOTION OF SCIENCE.

THE case of the Commissioners of Inland Revenue *v.* Forrest (the latter representing the Institution of Civil Engineers), which was finally decided on the 1st inst. by the House of Lords, is of great importance to all scientific corporations, associations, and institutions in this country, and, incidentally, the judgments cannot fail to interest, and possibly also to amuse, men of science, because it became necessary for their Lordships to consider what is science, or, rather, what the Legislature meant by the word science in a particular statute. Shorn of all technicality, the question was whether the Institution of Civil Engineers was liable to pay income-tax under the Revenue Act of 1885, section 11 of which was framed with the object of imposing a duty of 5 per cent. on the yearly value, income, or profits of bodies which escape probate, legacy, and succession duties, inasmuch as they never die and have no legal heirs or successors. The net was thrown with the object of catching trading corporations, companies, and associations, and compelling them to pay, in the shape of an annual impost, an equivalent for the various death duties levied on private individuals. The Act imposing this tax, however, exempted different classes of associations, and notably in sub-section 3 of section 11 it exempted all property the income or profit of which is applied for religious or charitable purposes, "or for the promotion of education, literature, science, or the fine arts." The whole question therefore resolved itself into this: Is the Institution of Civil Engineers an association "for the promotion of science"? The Commissioners thought it was not, in the sense used in the Act; Lord Coleridge and Mr. Justice (now Lord) Field sitting in one Court agreed with the Commissioners; Lord Justice Lopes in the Court of Appeal, and the Lord Chancellor in the House of Lords, were of the same opinion; but Lord Esher and Lord Justice Fry in the Court of Appeal, and Lord Watson and Lord Macnaghten in the House of Lords, held that the Institution was one for the promotion of science, and therefore exempt from the tax. The Institution therefore had a majority of the judges in the Court of Appeal and in the House of Lords, and it is now the law of England, until the Legislature chooses to alter it, that the Institution and all similar associations and bodies are exempt from this tax. Science, and, indeed, literature and the fine arts as well, owe a debt of gratitude to the Institution for its sturdy stand against the demand for payment. Although it is successful, its costs, over and above what it will receive from the Crown as the losing party, would, if invested, probably yield an income sufficient to satisfy the demand made upon it; by continuing the fight it has been the means of relieving the revenues of every association of the kind in the country from a burden of 5 per cent. per annum, an impost which in some cases would be intolerable, and would perhaps lead to the extinction of many struggling associations which are worthy of more support than they receive. In a sense, all science is relieved of a tax, and this it owes to the Institution of Civil Engineers.

We have said that the question turned on the meaning to be attached to the phrase "promotion of science," and ultimately to the word "science." The consideration of this question was complicated by the circumstance that in 1843 an Act was passed for dealing with the application of local rating (the Act of 1885, which was in question in this case, dealt wholly with Imperial taxation) to "exclusively" scientific and literary institutions supported wholly or in part by voluntary contributions. Under this Act it has been decided, for example, that the Zoological Society and the Russell Institution are liable to local rates, and it was against decisions such as these, and the instinct of judges to seek for a precedent, that the Institution of Civil Engineers had to fight in the present instance. Lord Macnaghten, however, boldly threw over the Act of 1843 and the decisions under it altogether, and refused to regard them as throwing any light on the Act of 1885. It referred, he said, merely to local rates, exemption from which is an invidious distinction, and throws a burden on everyone in the neighbourhood; while the present case being one of Imperial taxation, the range of exemption is far more extensive, and the conditions far more liberal.

The previous statute, and all the decisions under it, being thus disposed of, the judges were deprived of precedents, and had to answer for themselves what was science in the intention of the Legislature in 1885. Most intelligent people have a satisfactory working definition of the word; but it evidently perplexed the keen and experienced legal intellects of the judges in the House of Lords. The Lord Chancellor thought it could not, in this place, be equivalent to knowledge, because this would exempt almost every institution in the country, but that it did refer to science generally, and not to any particular branch of it. The Institution was, he argued, established for the benefit and interest of civil engineers, and not directly (though, no doubt, indirectly) for the advantage of the whole community. "I think a member of it makes a very good bargain for himself in becoming a member of it," and hence he did not regard it as exempt from taxation. Lord Watson took quite a different view, without going largely into questions of definition. It was indisputable, he said, that there was a science of civil engineering, that its development is of the utmost consequence to the national interests, that the labours of the Institution are of value to the profession at large, and constitute a substantial addition to the sum of human knowledge, and that it would be difficult to say what more effective measures could be adopted for the promotion of engineering science than those of the Institution. He found, therefore, that the latter applied its income, not to the professional ends of individuals, but for "the promotion of science," and that it was entitled to the exemption. Lord Macnaghten faced the question of the meaning of the word "science" in the Act:—

"I see no reason why it should be confined to pure or speculative science. The expression plainly includes applied science, and it was intended, I think, to denote a particular branch of science, as well as universal science or science generally."

This being his view, Lord Macnaghten, like Lord Watson, found no difficulty in arriving at the conclusion

that the Institution of Civil Engineers did in fact promote science:—

"Substantially, as it seems to me, the whole of the Society's income is applied to the promotion of science. My Lords, I cannot conceive in what better way the promotion of mechanical science, and in particular of those branches of mechanical science which lie within the province of civil engineering, could be effected. I cannot doubt that by means of the discussions on the papers read at the ordinary meetings of the Society much new light has been thrown on scientific questions, and much knowledge, which would otherwise have perished, has been preserved. I see no trace of a selfish or illiberal spirit in the proceedings of the Society, nor do I find anything to lead me to suppose that its property and income are applied otherwise than *bonâ fide* for the promotion of science. The action of the Society may incidentally benefit the profession to which its members belong—I have no doubt that is so—but I agree with the Master of the Rolls in thinking that 'that which this Society does is something higher and larger than the mere education of students and others for the profession of civil engineers.'"

The admirable definition of the object of the Institution, embodied in the charter of 1828, was stated in the course of one of the judgments to have been drafted by Thomas Tredgold. The Institution, it says, is established for the purpose of

"the general advancement of mechanical science, and more particularly for promoting the acquisition of that species of knowledge which constitutes the profession of a civil engineer, being the art of directing the great sources of power in nature for the use and convenience of man, as the means of production and of traffic in States both for external and internal trade, as applied in the construction of roads, bridges, aqueducts, canals, river navigation, and docks, for internal intercourse and exchange, and in the construction of ports, harbours, moles, breakwaters, and lighthouses, and in the art of navigation by artificial power for the purposes of commerce, and in the construction and adaptation of machinery, and in the drainage of cities and towns."

It is only right to say, in conclusion, that the utility of the work done by the Institution was admitted in the warmest manner by those judges who found themselves compelled to decide against its claim to exemption, now happily established.

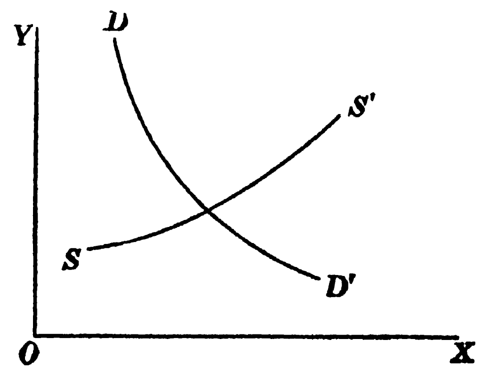
PRINCIPLES OF ECONOMICS.

Principles of Economics. Vol. I. By Prof. Alfred Marshall. (London: Macmillan and Co., 1890.)

ECONOMICS admit of being reduced to principles more than other sciences dealing with human actions, for the reason which Prof. Marshall has thus expressed: "Wide as are the interests of which the economist takes account when applying his doctrines to practice, the centre of his work is a body of systematic reasoning as to the quantities of measurable motives." These measurable motives are not necessarily self-interested: "The range of economic measurement may gradually extend to much philanthropic action." Even now the supply of labour and of capital is largely due to the motive of family affection. The uniformities of action resulting from such measurable motives may be regarded as the laws of motion in what Jevons called *the mechanics of industry*—a science which Prof. Marshall has cultivated with more success than any of his predecessors, owing to an unexampled combination of antithetical powers, the comprehensive grasp of mathematical reasoning, and the careful handling in detail of the observed facts.

As in physical mechanics innumerable conditions may be comprehended under the principle of virtual velocity, so also there is a unifying principle in the mechanics of industry. "Most economic problems have a kernel relating to the equilibrium of demand and supply." It is the peculiar merit of Prof. Marshall's arrangement to treat the law of supply and demand generally, before applying it to particular "markets," such as that relating to labour. It is here that he differs most from Mill, who seems to put asunder what the nature of things has joined together under one law—distribution and exchange. If Prof. Marshall's conception does not come as a surprise to his readers, it must be considered that he himself, in published and unpublished writings, has prepared the scientific world to accept his view. The services of others, particularly Prof. Walras, in improving upon the old wooden conception of distribution are not to be forgotten. Still it is true that, as far as we know, Prof. Marshall is the first adequately to treat what he has elsewhere called the pure theory of domestic (as opposed to international) value; uniting in a comprehensive view the doctrine of final utility, which Jevons and other recent writers have made prominent, with the equally eternal verities relating to "cost of production," which are connected with the name of Ricardo. The "theorems of Ricardo and Marshall" are rightly coupled by Signor Pantaleoni in his masterly "Principii di Economia Pura."

The relation between cost of production and demand is thus expressed by Prof. Marshall, following Cournot.



In the annexed diagram the abscissa indicates the amount of a product, and the ordinate the price thereof. DD′ is the demand curve, representing the quantity of the product which is demanded at each price; SS′ the supply curve, representing the quantity which is offered at each price. The intersection of these curves determines the equilibrium of the *market*—a generic term used in a wide sense, covering the temporary equilibrium of a fish-market and those slow processes of competition which it requires a generation to work out.

From this point of view is apparent the inaccuracy of those who describe value as altogether an affair of final utility, and speak of Ricardo as being "preposterous" in the classic sense of putting the cart before the horse. To use our own illustration, these economists might be compared to a physicist who should insist that in the determination of the position at which a balloon reaches

equilibrium, the buoyant gas plays a more important part than the heavy car. To be sure balloons could not go up without gas; whereas they might, and sometimes do, without a car. Still, from a mathematical point of view, we submit, it is legitimate to attribute to the positive and negative forces a "fundamental symmetry"—as Prof. Marshall characterizes the equilibrating motives towards utility and from *disutility*. By parity of reasoning they also are to be condemned who, neglecting final utility, worship only cost of production. But it may well be doubed whether this form of what we may call the monophysite heresy in regard to the doctrine of value is attributable in a serious degree to Ricardo. It is tenable that

"the older economists seem to have been rightly guided by their intuition when they silently determined that the forces of supply were those the study of which was the more urgent and involved the greater difficulty."

The theory of cost of production would be easy if all economic action were as simple as in the case of one who goes on picking and eating blackberries until the labour of picking just compensates the pleasure of eating. The concrete case is greatly complicated by the element of *time*. Under cost of production we must include the less direct efforts and sacrifices, such as that of the parent who, vicariously competing in the labour market, supplies an educated employer or artisan to that occupation where there appears to be the best opening. Before the education is completed perhaps the opening has ceased to be the best. The normal tendency to equilibrium is thus ever interrupted by the introduction of some new condition:—

"There is a constant tendency of the surface of the sea towards a position of rest, but the moon and sun are always shifting their places and always therefore changing the conditions by which the equilibrium of the sea is governed; and meanwhile there are ceaseless currents of the raging winds; the surface is always tending towards a position of normal equilibrium, but never attains it."

In this troubled scene everything is in flux, and subject to the theory of fluxions:—

"The amount of the commodity and its price, the amounts of the several factors or agents of production used in making it and their prices—all these elements *mutually determine one another* [we italicize words which convey a lesson which has never before been taught thoroughly], and if an external cause should alter any one of them, the effect of the disturbance extends to all the others."

If there is any of the economic variables of which it may be said that it is determined without determining, it might be the old Ricardian "inherent properties" of land, about which Prof. Marshall has much that is new to say. As for the quasi-rents which more recent theory has evolved, they are all affected with the fallacy which Prof. Marshall's scientific method is particularly adapted to guard against—the treating as constant quantities which are variable. The "margin" from which the remuneration in any skilled occupation is measured is itself a variable, varying with the remuneration; because the supply of competitors is dependent upon the prospect held out by the great prizes in that occupation. The apologist of the existing economic *régime* who defends the profits of the successful employer as being a rent of ability, the Socialist who attacks the interest of capital as being a rent of opportunity, are alike building their insecure constructions upon the sands of a shifting coast-line.

We are prevented by the narrowness of our limits from exhibiting the important results obtained by the full treatment of the subject to which we have barely adverted—namely, the *simultaneous* determination both of the relative value of products, and the remuneration of producers, in a *régime* of free competition. We must hasten on to observe that the same methods of abstract reasoning are applicable, *mutatis mutandis*, to a *régime* of monopoly. This case is important, not only for itself, on account of the prevalence of trusts and monopolies, but also by reason of the analogy between governmental and monopolistic action. Prof. Marshall, by original methods, deduces the startling conclusion

"that it might even be for the advantage of the community that the Government should levy taxes on commodities which obey the law of diminishing return, and spend part of the proceeds on bounties to commodities which obey the law of increasing return."

This reasoning is, of course, very abstract; abstracting the indirect evils which governmental interference may produce. But it at least suffices to destroy the *a priori* presumptions in favour of "economic harmonies" and unqualified *laissez faire*. Prof. Marshall reaches these and other important conclusions by estimating the "consumers' rent"—that is, the advantage which consumers derive from a fall of price. In connection with this subject we should advert to his beautiful theory of the elasticity of demand. The more elastic or expansive demand is, the greater is the increase of consumers' rent due to a given fall of price.

We should like to dwell upon the practical importance of these conceptions. But it is impossible here to analyze a work almost every page of which presents a new idea. We must be content with indicating methods as distinguished from particular theories. The mathematical method appears to be established in its proper position by the precept and example of Prof. Marshall:—

"Our observations of nature, in the moral as in the physical world, relate not so much to aggregate quantities as to increments of quantities. . . . It is not easy to get a clear full view of continuity in this aspect without the aid either of mathematical symbols or diagrams." . . .

Prof. Marshall expresses some preference for diagrams:—

"Experience seems to show that they give a firmer grasp of many important principles than can be got without their aid, and that there are many problems of pure theory which no one who has once learnt to use diagrams will willingly handle in any other way."

Developing a metaphor suggested by our author, we might compare these mechanical aids to reason to the machinery employed in material production. Appliances useful to one producer will not be equally so to another. There is what Prof. Marshall calls the "law of substitution," according to which each producer selects the expedients most serviceable in his own case. Usefulness will depend much on familiarity. "It seems doubtful whether anyone spends his time well in reading lengthy translations of economic doctrines into mathematics that have not been made by himself."

By way of illustrating this character of intellectual

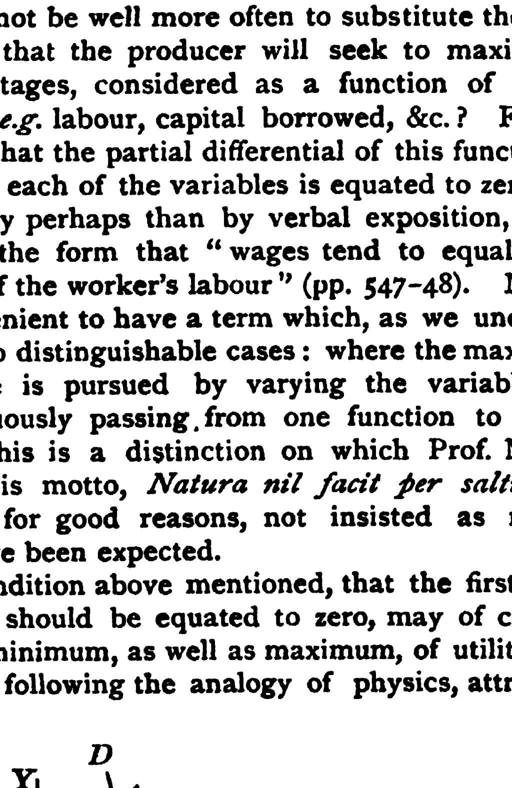
machinery, we shall advert to some passages which seem to us to contain things which some would rather have expressed otherwise. In the first note of his "Mathematical Appendix," Prof. Marshall, referring to the weakened motive power of distant or deferred pleasures, thus writes:—

"Let h be a pleasure of which the probability is p, and which will occur, if at all, at time t. Let r be the rate of interest per unit which must be added to present pleasures before comparing them to future, and let $R = 1 + r$; then the present value of the pleasure is phR^{-t}."

Should it not be more clearly expressed here, or elsewhere, that this formula holds only of marginal utility, and that it is not a general psychological truth irrespective of conditions imposed by a money market? For instance, I anticipate a series of pleasant hours extended over several weeks during which I shall be occupied in mastering this stupendous work. But I do not observe that the anticipated pleasure of the third week differs from that of the first according to an exponential law of variation.

Another verbal modification is suggested by the frequent use of the "law of substitution"; which, as above intimated, imports that producers will, as a rule, substitute the less for the more expensive methods of production. Might it not be well more often to substitute the simpler statement that the producer will seek to maximize his net advantages, considered as a function of different variables, *e.g.* labour, capital borrowed, &c.? From the principle that the partial differential of this function with respect to each of the variables is equated to zero follow, more easily perhaps than by verbal exposition, propositions of the form that "wages tend to equal the net produce of the worker's labour" (pp. 547-48). No doubt it is convenient to have a term which, as we understand, covers two distinguishable cases: where the maximum of advantage is pursued by varying the variable, or by discontinuously passing from one function to another. Indeed, this is a distinction on which Prof. Marshall, true to his motto, *Natura nil facit per saltum*, has, probably for good reasons, not insisted as much as might have been expected.

The condition above mentioned, that the first term of variation should be equated to zero, may of course indicate a minimum, as well as maximum, of utility. Prof. Marshall, following the analogy of physics, attributes to



a minimum the property of equilibrium. For example, in the case represented by the annexed figure, which corresponds to the author's Fig. 20 (p. 424)—SS' and DD' being, as above explained, the supply and demand curves —Prof. Marshall says, "H and L are points of stable equilibrium, and K is a point of unstable equilibrium." This interpretation may appear doubtful, when we consider that the supply curve, when *descending*, is the locus of *minimum advantage* for the producer. At any assigned price, *e.g.* SH or BK, this locus represents the very worst arrangement for the producer, the very bottom of the trough, where he cannot, even theoretically, be supposed content to stay. If this view be accepted, some doubt will be thrown on the "theory of multiple positions of equilibrium" (*ibid.*). A solution of these little difficulties, consistent with the author's conclusions, will probably be found by those who follow out the hints afforded by his pregnant notes.

A comparison with the eminent mathematical economists Messrs. Auspitz and Lieben suggests one more scruple. Those theorists regard the demand curve as the *envelope* of a series of discontinuous curves, each of the sort contemplated by Prof. Marshall, corresponding to different scales of living. This conception, if accepted as important, might have some bearing on the theory of "consumers' rent."

But in dwelling on such technical points we should run the risk of conveying an unfair impression of the worth and accuracy of Prof. Marshall's work. The theoretical subtleties about which a difference of opinion is possible "have a very narrow range of practical bearing." Prof. Marshall is the first to admit of his theory, "when pushed to its more remote and intricate logical consequences, especially those connected with multiple position of equilibrium, that it slips away from the conditions of real life, and soon ceases to be of much service in dealing with practical problems." Besides, this is a subject on which, as Disraeli said, the author is much more likely to be right than the critic. In this sort of mixed mathematics the authority of one who is, above all others, conversant with both ingredients of the mixture is almost supreme. He, of all mathematical economists, has best complied with his own maxim that the economist, while he employs "systematic reasoning as to the quantities of measurable motives, ... must never lose sight of the real issues of life; and these are all, with scarcely any important exceptions, affected more or less by motives that are not measurable."

Of the two parts of the economist's work we have here dwelt somewhat exclusively on that which best admits of being viewed synoptically, the more abstract side. We must be content with recording, without illustrating, the judgment that the moral and mathematical parts of Prof. Marshall's work are on a level of excellence. He not only applies the differential calculus to measure increments such as "a shilling's worth of happiness," but he also brings a higher faculty to judge of goods which cannot be measured by money, such as "the fulness and nobility of human life," "a pure heart, and a love towards God and man." He renders to the queen of the sciences the things which belong to her province, and to the spiritual side of our nature things which transcend man's power of calculation.

F. Y. E.

SADI CARNOT'S ESSAY.

Reflexions on the Motive Power of Heat, &c. From the original French of N.-L.-S. Carnot. Edited by R. H. Thurston, M.A., LL.D., Dr. Engg., Director of Sibley College, Cornell University; "Officier de l'Instruction Publique de France"; etc., etc., etc. (London: Macmillan and Co., 1890.)

NE soyons pas exigeants: la perfection est si rare! This is one of the rules laid down by Sadi Carnot for his own guidance:—and we will endeavour, as far as possible, to give his present Editor and Translator the benefit of it. They need it sadly.

There is no Press-mark on the book before us, but it bears internal evidence of having been printed in the United States. Surely there are few, if any, British printers who, at the end of a line, would divide words into such startling fragments as knowl-edge, quan-tity, uncer-tainties, transfor-mation, mecha-nism, hypothe-sis, mo-tive, &c., &c.!

The book is (described as) a "Translation of the famous work of Carnot." It is made from the Reprint of 1878, to which Carnot's surviving brother had added a slight but very interesting biographical sketch of the Author, as well as some extremely important excerpts from his unpublished MS. These additions are translated also. An exceedingly inconvenient arrangement, the separation of the longer foot-notes from the text of Carnot's Essay and their collection at the end of the book, is explained as "*simply a matter of convenience in book-making.*" We presume, though it is not stated, that the quite unnecessary reprinting of Sir W. Thomson's paper, on Carnot's Theory, is also a simple matter of book-making!

The book is prefaced by a *Publisher's Note*, a *Note by the Editor*, and an Essay (also by the Editor) on *The Work of Sadi Carnot*. We forbear to comment on the first two of these. On the third we would make two remarks:—

(1) It is somewhat difficult for us who have lost so recently (and from our little island alone) men like Faraday, Joule, and Clerk-Maxwell, to feel the full justice of the statement that Sadi Carnot was perhaps "*the greatest genius, in the department of physical science at least, that this century has produced.*" Exaggeration like this leads the reader to doubt the judicial competence of the man who employs it. We yield to none in our estimation of the value and originality of Carnot's work:—but such feelings must not blind us to the relative merits of others.

(2) Our opinion of the competence of the Editor is not enhanced by his informing us that at eighteen Hamilton "conceived" Quaternions (he means, presumably, the *Characteristic Function*, a totally different thing); nor by his even more striking novelties in scientific history.

As to the Translation itself, two questions arise. Was it necessary, and is it satisfactorily carried out? We have much doubt as to the propriety of translating *any* scientific work from French, German, Italian, or Latin, into English. If a man cannot read it in the original, his ignorance (all but criminal) should be punished. But if the propriety of translating at all is doubtful, the possibility of procuring a really adequate translation is much more doubtful. It may be confidently laid down, as an axiom, that no adequate translation of a really scientific work can be made except by a man whose knowledge of the subject is at least nearly on a par with that of the Author. Such men are always scarce, and can usually employ their time more profitably than in reproducing, in a different idiom, the thoughts of another.

But if a translation must be made, accuracy is essential. Change of idiom is inevitable, change of meaning (however slight) intolerable. Let us see how the present Translator stands in this respect. The task before him was a difficult one, for Carnot's reasoning is in several places somewhat delicate; and in one or two places a little obscure. Failure was therefore *à priori* more probable than success; and, while even complete success was not likely to be of much use to any one, failure was certain to make the result misleading:—*i.e.* a great deal worse than useless.

One of the first passages which we chanced to read, on opening the book (p. 21), runs thus:—

"Scarcely a year had passed when the proscription, *which included* the Director, *obliged him to give up his life, or at least his liberty, to* the conspirators of fructidor. . . . (Our mother) *fled to* St. Omer, *with* her family, while her husband *was exiled* to Switzerland, then to Germany."

Compare the words we have italicised with the corresponding ones in the original (given below):—and then judge of the fitness of the perpetrator for the translation of a work of real difficulty and of particular nicety of reasoning.

"Une année à peine s'était écoulée quand la proscription *vint frapper* le Directeur, *obligé de dérober sa vie, tout au moins sa liberté, aux* conspirateurs de fructidor. . . . (Notre mère) *se réfugia* à Saint-Omer, *dans* sa famille, tandis que son mari *s'exilait* en Suisse, puis en Allemagne."

There is more than one first-class blunder for every single line in the passage translated!

On p. 26 we read:—

for his name . . . . was henceforth the cause of his advancement (*sic*) being long delayed."

Who, attempting to put this bad English back again into French, could possibly hope to reproduce the original? It runs thus:—

". . . . car son nom . . . . devait suffire pour que désormais il n'attendît son avancement que de la longeur du temps."

The word "Anvers," which occurs more than once, is not translated at all; while for "plusieurs places fortes" we find (p. 26) the extraordinary substitute (we cannot call it an *equivalent*) "many *trying* places"!

After these experiences we might have dispensed with any further examination of the book. But we felt bound to examine at least a part of the translation of the Essay. We selected as a first test a well-known passage, in which Carnot elegantly meets a supposed objection to his reasoning. The original is as follows:—

". . . la quantité de chaleur nécessaire pour reporter le liquide à sa température première sera aussi infiniment petite et négligeable relativement à celle qui est néces-

saire pour donner naissance à la vapeur, quantité toujours finie."

The meaning is absolutely clear, the contrast being between an infinitesimal, and an essentially *finite*, quantity of heat. What sort of notion of Carnot's reasoning can he have who *translates* the passage as below (p. 59)?

"The quantity of heat necessary to raise the liquid to its former temperature will be also indefinitely small and unimportant relatively to that which is necessary to produce steam—a quantity always *limited*."

The sting is, of course, in the tail:—its proper place. But this one word suffices to destroy the entire argument.

In the translation of the foot-note (preparatory to the discussion of the air-engine) where Carnot gives experimental facts as to the temperature-effects of condensation and rarefaction of gases, we have, among other blunders, a really amusing one. Carnot says:—

". . . l'air qui vient toucher immédiatement la *boule* du thermomètre reprend peut-être par son choc contre cette *boule*, ou plutôt par l'effet du détour qu'il est forcé de prendre à sa rencontre, une densité &c."

The translator would almost seem to have thought that a game at Bowls is here alluded to; for he gives the passage in the form:—

"The air which has just touched the *bowl* of the thermometer possibly takes again by its collision with this *bowl*, or rather by the effect of the *détour* which it is forced to make by its *rencounter*, a density &c."

Since so much of this passage has been left untranslated, it is to be regretted that the whole sentence (and, for that matter, the whole Essay) has not been left in its own strikingly original and well-chosen language.

Many years ago we met with a book something like this one. The writer was translating from Laplace, and rendered the passage

"Si l'on prend, pour unité de temps, la seconde décimale ou la cent-millième partie du jour moyen . . ."

in the following exquisite fashion:—

"If we take the *second decimal*, or the $\frac{1}{100000}$ of the mean day as the unity of time . . ."

This is perhaps finer than anything in Mr. Thurston's translation, but he occasionally rises nearly to its level.

We conclude, as we commenced, with a maxim of Carnot's:—

De l'indulgence, de l'indulgence!

P. G. T.

TRIASSIC FISHES AND PLANTS.

Fossil Fishes and Fossil Plants of the Triassic Rocks of New Jersey and the Connecticut Valley. By J. S. Newberry. (Washington: Government Printing Office, 1888.)

THE fourteenth of the splendid series of monographs issued, and so liberally distributed, by the U.S Geological Survey, is by Prof. Newberry, and deals with the fossil fishes and plants of the east coast Triassic areas known as the Palisades and the Connecticut Valley. Their red shales, sandstones, and conglomerates occur for the most part in narrow basins parallel to the coast or coast ranges, intersected by sheets and dykes of diabase, and average about 5000 feet in thickness. In a very few spots the almost barren shales are charged with carbonaceous matter, and in these plant and fish remains have been met with. The two areas are separated by the wide Hudson Valley tract of older rocks, and are distinguished by all the Palisade beds dipping at an angle of 3° to 15° west, while the Connecticut beds dip as uniformly to the east. Various theories accounting for their deposition are discussed, but the simplest would be to regard them as local deposits of a flat, shallow, sandy, thoroughly sheltered coast-line, subjected to heavy tides. With gradual and intermittent subsidence, and consequent continued encroachment on the land, most extensive beds of varying fineness might be formed. A dip, such as that observed, would ensue, as the beds passed successively under low-water mark, and fell under pressure of the sea into the ordinary slopes of a shelving shore. Sun cracks, ripple marks, and footprints would be formed in each bed in the belt exposed between the high-water marks of neap and spring tides. That the deposits originally swarmed with prey is evident from the footprints of nearly 100 varieties of animals, only a part of which were perhaps amphibious, which made them their promenade. Almost every trace, however, of such organisms as mollusca, annelids, crustacea, and plants, have disappeared.

The second part of the memoir, relating to the fossil fishes, occupies about two-thirds of the volume, and commences with some preliminary remarks on the gradual discovery of the fauna under consideration. Some of these fishes were among the first fossils to attract the attention of American geologists, and two species were figured and described by Agassiz in his "Poissons Fossiles." To Messrs. W. C. and J. H. Redfield, however, palæontology is mainly indebted for the knowledge of the fauna previous to the researches of Dr. Newberry; and their original collection, now in the Yale College Museum, has furnished much of the material for the present memoir. Dr. Newberry himself undertook excavations at Boonton, N.J., in 1866, thus obtaining a large series of specimens for the Columbia College, New York; and numerous discoveries have been more recently made in other localities, by various investigators, to whom the author expresses indebtedness.

The detailed descriptions of the genera and species, illustrated by no less than twenty plates, form the first satisfactory account of the American Triassic fish-fauna; and this will prove of great value for comparison with the corresponding assemblages of fishes met with elsewhere. To the Lepidosteoid family of Lepidotidæ are assigned *Ischypterus*, with eighteen species, *Catopterus*, with six species, *Acentrophorus*, *Dictyopyge*, and *Ptycholepis*, each with one species; while the Crossopterygian family of Cœlacanthidæ is represented by a peculiar genus and species—*Diplurus longicaudatus*. Some interesting general remarks upon each genus precede the more detailed discussion of the various species; and, in the case at least of *Ischypterus*, we are inclined to agree with the author when he suggests that future researches may tend to reduce the number of specific types he at present feels justified in recognizing. In such cases as the present,

it is most difficult to distinguish the results of crushing and disintegration from actual specific characters; and even in a formation so little disturbed as the black Triassic shale in which these fishes are entombed, the apparent form of the head and trunk cannot always be relied upon in specific diagnoses.

Ischypterus is undoubtedly identical with *Semionotus*, as Dr. Newberry suspects, and is thus represented both in America, Europe, and South Africa. Ichthyologists will doubtless also agree with the systematic position in which the author places the genus. To us, however, it appears that this determination was more conclusively proved by the researches of Dr. Traquair in 1877, when he offered to the Geological Society some detailed remarks on the osteology of the fish; and on that occasion the intimate connection between *Ischypterus* and *Semionotus* was equally pointed out. Each of the species is illustrated by at least one figure, and good reason is given for assigning to one of the larger forms the supposed fragment of a *Tetragonolepis*, brought from Virginia by Lyell.

Catopterus and *Dictyopyge* are retained as distinct genera, in accordance with the usual custom; and then follow two interesting types which the author himself has added to the list. A very distinct species of *Ptycholepis* is described from Durham, Conn., and an equally peculiar species of *Acentrophorus* is made known from the Chicopee Falls, Mass. Of these genera, the first has hitherto been known chiefly from the English and German Lias, though also rarely obtained from the Austrian Keuper; while the second has previously been found only in the Permian magnesian limestone and marl slate of Durham, England.

A preliminary definition of the Cœlacanth fish *Diplurus longicaudatus* was given by Dr. Newberry several years ago; and the detailed description and figure now published are a welcome addition to our knowledge of the group to which the fish belongs. The finest specimen is nearly complete, and is only disappointing in the matter of cranial osteology. The largest specimen discovered measured about three feet in length, thus exceeding in size any Cœlacanth hitherto met with below the Jurassic.

The third portion of the memoir deals with the fossil plants, only seventeen species of which have been brought together. These confirm the views of Saporta as to the infra-lias, or, at most, Keuper, age of the formation, arrived at from a study of the far more important series described by Fontaine in the sixth monograph of the Survey, issued in 1883; a series procured from the coal-bearing outliers of the same age in Virginia and Carolina.

Of plants common to the Rhætic of Europe we have *Clathropteris platyphylla*, *Cheirolepis Münsteri*, *Otozamites latior*, *O. brevifolius*, two species of *Pachyphyllum* hardly separable from *P. peregrinum*, *Equisetum Rogersi*, claimed by Saporta to be identical with *E. arenaceum*, and the doubtful stems well known in many Triassic rocks, sometimes referred to Calamites, but here referred to *Equisetum Meriani*, Brong., and *Schizoneura*.

Among the novelties is *Dendrophycus triassicus*, a supposed algoid with a cabbage-like leaf destitute of transverse nerves. From the fact that there is in the British Museum an identical structure, from a gritty Tertiary limestone of Mull, which can hardly be organic, we should question the vegetable nature of this fossil, without, however, being able to suggest any other plausible origin. There is a new Cycadinocarpus, founded on a compressed cycas-looking nut, possibly the fruit of one of the Otozamites; and the obscure plant, referred to by Fontaine under the misleading name of *Bambusium Carolinense*, now called *Zoperia simplex*. Whether, as suggested by the author, this may prove to be an aquatic Monocotyledon—"a kind of gigantic Schollera"—there are no sufficient materials for discussing. It is somewhat surprising to find *Baiera Münsteriana* located among the Cryptogams, as there are so many forms connecting it with Ginkgo, all possessing the remarkable twin fibro-vascular bundles in the petiole which result in the symmetrically cleft leaf, that its position is scarcely doubtful. We prefer that the Cycads should precede the Conifers, but in so small an assemblage of species, their want of arrangement is of no great importance.

A. S. W. AND J. S. G.

SEA ANEMONES OF THE NORTH ATLANTIC.

Den Norske Nordhavs-Expedition, 1876–1878. *XIX. Zoologi: Actinida.* Ved D. C. Danielssen. Med 25 Plader og 1 Kart. (Christiania: Grondahl and Son's Bogtrykkerl, 1890.)

ANOTHER part of the General Report of the Norwegian North Atlantic Expedition has just been published, containing a memoir on the Actinida of the North Atlantic, by D. C. Danielssen. It will be remembered that this fine series of memoirs is published under the sanction of the Norwegian Government, and with some assistance from their Treasury. They have been distributed to very many of the Academies and learned Societies of the world, and reflect immense credit on the zeal and intelligence of the Norwegian naturalists.

All the specimens described by Dr. D. C. Danielssen in this memoir were collected from deep water, and most of them from the "cold area." These anemones, for the greater part, proved capable of accommodating themselves to changes of habit and temperature, and it was therefore possible to keep them alive for a considerable period, during which their external characteristics were observed and their portraits taken. That, despite the heavy rolling sea so generally met with in the North Atlantic, the artist has done his part well, is proved by a glance at the first five plates which accompany this memoir, which have been printed in colours by Werner and Winter, of Frankfort-on-the-Main.

This memoir represents the first serious attempt, since the publication of Richard Hertwig's Report on the *Challenger* Actinaria, to describe the sea anemones of an extended area, taking their anatomical features as the basis of their classification; and it seems to us to justify the remark that a very much larger series of facts must be noted before an even fairly plausible scheme of classification of this group can be formulated. No doubt the systems of Gosse and Andrès, based for the most part on mere external characteristics, have had their day; but no new scheme to take their place has yet been properly developed; a wider and closer anatomical investigation of even well-known species must be undertaken ere this can be looked for.

Perhaps this will in some measure account for the fact that of the Actiniæ collected during the expedition, thirty-nine out of forty-one are described as new species, for which eighteen new genera are diagnosed, and five new families are formed. The large majority of these new forms belong, as might be expected, to the Hexactiniæ of Hertwig, but some belong to the Edwardsiæ, Zoantheæ, and Ceriantheæ; while a new tribe has been provisionally made to receive two forms (Fenja and Ægir), not at first sight clearly appertaining to the Actinaria. These forms have elongated, cylindrical, vermiform bodies, with an apparently complete body cavity; the oral disk is surrounded with tentacles, and opens into an œsophagus, which is continued into a closed intestine, which opens at the aboral end of the body. There are twelve septal chambers, complete in themselves, with twelve pore openings around the anal opening.

In *Fenja mirabilis* the body is 70 mm. in length and 15 mm. in breadth at the anterior extremity, whilst the posterior part is rather narrower; the surface of the body is smooth and shining.

In *Ægir frigidus* the animal is surrounded with a mucous investment, and the body is but 30 mm. in length; from 8 to 10 mm. in breadth at the anterior extremity, to 4 to 5 mm. in breadth at the somewhat rounded posterior extremity. While in Fenja the ovaries do not materially differ from the type in the Actinida, those in Ægir greatly approach the form generally met with in the Alcyonida.

It would seem useless to speculate as to the position these strange forms must occupy until something more is known of their structure and something of their development. Dr. Danielssen writes that, if the cœlom is to be regarded as the distinctive feature, then it is evident they cannot be placed among the Cœlenterata; but he adds that perhaps too much stress has been laid on the so-called gastro-vascular apparatus as a systematic feature in this group, and that what is called the œsophagus in Actinida is possibly a rudimentary intestinal formation.

We have alluded to these two forms in some detail as being of very special interest, but an almost equal interest attaches to others which are also to be found described, but which our space forbids us to do more than thus generally refer to. In addition to the coloured plates representing the new species, there are nineteen with the various anatomical details, making this memoir one of the best illustrated of the series. It follows so closely on the memoir on the Alcyonida by the same distinguished author, that we cannot but express our admiration for the energy he displays in working out the natural history of the Norwegian coast, which is now better known than that of our own shores.

OUR BOOK SHELF.

Smithsonian Report, 1887. (Washington: Government Printing Office.)

THIS important publication is increasing year by year in value, in consequence of the pains taken to increase the quantity and quality of the records of progress in the various sciences. In the present volume it brings the records of the Institution down to June 30, 1887. We find the proceedings of the Board of Regents and of the Executive Committee, the Report of the Secretary on the general work of the establishment, the National Museum, and the Bureau of Ethnology. But there is very much more than this, although these matters are by no means of merely local interest. The progress of astronomy, North American geology and palæontology, vulcanology and seismology, geography and exploration, physics, chemistry, mineralogy, zoology, and anthropology, take up no less than 500 pages, and are admirably done. We should add that the record of each branch of science is accompanied by a full bibliography, which largely increases its usefulness. The miscellaneous papers this year deal chiefly with the Western mounds and Indian archæology.

Travels and Discoveries in North and Central Africa. By Henry Barth. (London: Ward, Lock, and Co., 1890.)

FORTY years ago Barth was invited to join a mission which the British Government was about to despatch to Central Africa. He accepted the invitation, and was absent from Europe nearly six years, in the course of which he travelled from Tripoli to Bórnu, and from Bórnu to Timbúktu. The account of his explorations, published in 1857 in German and English, was immediately recognized as one of the most important and fascinating of modern books of travel; and even now, after so long an interval, it has lost but little of its interest. In the present volume, which belongs to the Minerva Library, the first half of the great traveller's elaborate work is reproduced with many of the original illustrations. The books of travel by Darwin and Wallace, which have been reissued in the same series, differ considerably from that of Barth, who was not a naturalist; but, as Mr. Bettany, the editor, says, "to make up for this he is extremely rich in topographical, historical, and anthropological details." Mr. Bettany contributes to the volume a short introduction, in which he brings together some of the leading facts relating to Barth's career.

Weather Forecasting for the British Islands. By Captain Henry Toynbee, F.R.A.S., &c. (London: Edward Stanford, 1890.)

THIS is a most interesting and useful little book, and should be in the possession of all those who take any interest whatever in weather forecasting. It is written with the intention of showing what a single observer can do as regards this subject, supposing him to have a barometer, means for observing roughly the direction and force of the wind, and power to recognize cirrus clouds and the direction from which they are coming. To make the book more complete, the author has added some daily weather charts to illustrate the application of the principles and variations which occur in practice, and to show what can be learnt from them.

The Encyclopædia of Photography. By Walter E. Woodbury. (London: Iliffe and Son, 1890.)

THIS is the second part of the work we noticed before, to be completed in about twelve parts issued monthly. The ground covered is from B to Coffee Process, between which entries will be found information useful to all classes of photographers. Bromide paper, camera-bellows making, carbon process, may be mentioned as among the subjects most fully treated of. When completed, the work will contain over 1000 references, and be illustrated by about 200 explanatory sketches and diagrams by the author.

Japan and the Pacific. By Manjiro Inagaki, B.A. (Cantab.). (London: T. Fisher Unwin, 1890.)

THIS book, so far as it has any elements of interest, appeals rather to politicians than to students of science,

The subject with which the author deals is the relation of Japan to the Eastern Question, and therefore to England and Russia. It is a striking fact that such matters should be discussed in an English work by a native of Japan. Mr. Manjiro Inagaki cannot, however, be congratulated on the way in which he sets forth his ideas. His facts are thrown together so loosely that it is sometimes difficult to make out the propositions which he wishes to prove or to illustrate.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Indiscriminate Separation, under the Same Environment, a Cause of Divergence.

I HAVE accumulated a large body of facts indicating that separated fragments of a species, though exposed to the same environment, will in time become divergent. I find that, wherever a species possessing very low powers of migration is for many generations divided into a series of fragments by barriers that do not obstruct the distribution of surrounding species, more or less divergence arises in the separated portions of the species, though, in the same areas, there is no divergence in the environing species whose distribution is not obstructed. I still further find that, whenever the distances intervening between the different fragments are an approximate measure of the time and degree of separate breeding (as is frequently the case, as long as the divergence does not involve any physiological and psychological segregation), these distances are also an approximate measure of the degree of divergence.

The validity of this conclusion is called in question because it is inconsistent with the theory that all divergence is due to diversity of natural selection, and that all diversity of natural selection is due to exposure to different environments. The divergences in the cases above referred to, it is said, are probably due to differences in the environment that are not easily recognized. This was the explanation suggested by Darwin when the facts were reported to him in 1872. The division of a species into isolated portions did not seem to him to furnish any factor that could produce divergence unless it was aided by exposure to different external conditions. The same view is expressed in his "Origin of Species," sixth edition, p. 319.

My reply is twofold. (1) The theory that all the divergences in Sandwich Island land mollusks are due to differences in the environment requires us to believe that there are occult influences increasing in difference with each additional mile of separation, and that these influences control the natural selection of the mollusks, but have no influence on any of the other species occupying the same areas. A theory that involves so heavy an assumption cannot be received when a simpler theory is open to us. (2) I believe I can entirely remove this objection, urged against my conclusion on these purely theoretical grounds, by showing that there are certain causes of divergence, not depending on exposure to different environments, that are necessarily introduced by the division of a species into isolated groups; and that, under the influence of these causes, diversity of habits may arise producing diversity of natural selection, even while the fragments are exposed to the same environment.

I have elsewhere called attention to the fact that the independent breeding of separated groups, so far as we can judge, always tends to produce divergence; and I have shown that, when a species is indiscriminately broken into independent fragments, the tendency to divergence will, on the average, vary in direct proportion to the instability of the species, and in inverse proportion to the size of the fragments, for on these factors depends the probable degree of departure of the average characters of the fragment from the average character of the species previous to its being broken into fragments, and, therefore, the degree of segregation.

I wish now to show that the maintenance of certain classes of characters always belonging to an unbroken species is due to a form of selection that can continue only so long, and so far, as free crossing continues. Reflex selection is a formative principle, depending on the relations in which the members of an inter-generating group of organisms stand to each other, while they continue to inter-generate; but when two portions of an original species have become so divergent as to compete with each other in the same area without crossing, they form incipient species, and each belongs to the environment of the other. While they are members of the same inter-generating group, their mutual influence results in reflex selection, which maintains the correspondence with each other by which power to cross is preserved; while they are members of groups that do not cross, their mutual influence results in mutual selection that inevitably tends toward the preservation of variations that, through greater divergence, best escape from competition. I have elsewhere defined reflex selection as being the exclusive propagation of those better fitted to the relations in which the members of the same species stand to each other, resulting from the failure to propagate of those less fitted. Among those that are equally fitted to the environment of the species, and therefore equally preserved by natural selection, there is often great difference in the degrees of fitness for sustaining such relations to the rest of the species as will secure an opportunity to propagate. To this class of influences belong the different forms of sexual selection through which the sexual instincts and other sexual characters of the different sexes are kept in full coordination. In like manner we must believe that the pollen of any species is kept up to its full degree of potency by the constant selection which results from the failure to propagate of the individuals whose pollen is less potent or whose germs are more difficult to fertilize than the average. We cannot call this sexual selection; but we have to class it as the form of reflex selection through which the physiological co-ordination of the male and female elements with each other is so maintained as to secure full fertility. Again, there is a constant selection of animals that are suitably endowed with the recognition marks and calls by which the different members of the species know each other, and that have the corresponding instincts that lead them to associate with their own kind who are thus endowed. I have elsewhere called this principle of social co-ordination "social selection," and have classed it as a form of reflex selection.

There are several other forms of reflex selection. One of these secures harmony in the habits and modes of life of the different members of a freely inter-generating group of organisms; for individuals, whose habits are not sufficiently co-ordinated with those of the mass of the species to allow of their interbreeding with them, will fail of propagating. This we may call co-ordinative industrial selection. We are now prepared to understand one reason why independent breeding resulting from indiscriminate separation is in time transformed into segregation. Independent breeding is in its very nature the suspension, not only of one form, but of all forms of reflex selection between the separated portions of the species. The importance of the cessation of natural selection in producing the different stages of the degeneration of organs that are disappearing has been fully discussed by Prof. Romanes (see NATURE, vol. xli. p. 437, and previous communications there referred to), who points out that, as the power of the special form of heredity by which any organ is produced has been built up by the many generations of natural selection that have acted in favour of the organ, so the gradual weakening of that power follows the cessation of the natural selection. Prof. Weismann seems to appeal to the same principle when he attributes the disappearance of "rudimentary organs" to the action of "panmixia." Now, in the cessation of reflex selection which follows independent breeding, a similar principle is introduced, and the inevitable result must be the weakening of the power of heredity by which the portions of the species were held in correspondence with each other before their separation. I have elsewhere shown that separate breeding necessarily disturbs unstable adjustments; and we here see that the most stable of the adjustments by which each part of a species is kept in correspondence with every other part gradually becomes unstable under the continued influence of separation. Whenever a species is divided into two portions that do not interbreed, the four forms of reflex selection above described will cease to act between the two portions, and they will continue in sexual, social, physiological, and industrial harmony with each other, only in so far as the force of the old heredity holds them to the old standards. But the power of heredity in these respects will in time fail, if reflex selection is entirely removed. If the

separate breeding is long continued, incompatibility in all these respects tends gradually to arise; but it is manifest that incompatibility of industrial habits implies diversity in the forms of natural selection that shape each portion. I therefore maintain that separation which necessarily includes the cessation of reflex selection between the portions separated is a cause of segregation and divergence, and that it introduces diversity of natural selection, which is a still further cause of divergence.

Unless the separated portions of a species possess exactly the same average character (which we must believe is seldom, if ever, the case), separation must, from the first, be more or less segregative; and even in cases where the portions completely correspond in character (if there are any such cases), the cessation of reflex selection which is involved in the separate breeding, must result in segregration as soon as the power of heredity begins to weaken; and this is in due time followed by other forms of intensive segregation. I therefore conclude that indiscriminate separation may be regarded as a preliminary form of segregation (*i.e.* discriminate separation), and that in the nomenclature we ordinarily use both principles may be called "segregation" without confusion.

26, Concession, Osaka, Japan. JOHN T. GULICK.

The Affinities of *Heliopora cærulea*.

IN Prof. Moseley's admirable account of the structure and affinities of *Heliopora*, published in the Transactions of the Royal Society, 1876, and afterwards in the *Challenger* Reports, there occurs the following passage: ". . . directly the coral (*i.e. Heliopora*) was left at rest a swarm of a species of *Leucodora*, closely resembling *Leucodora nasuta*, which infests the coral and perforates it all over, expanded themselves at once."

This will probably explain the cause of the curious mistake that Mr. Saville Kent has made, in his letter published in last week's NATURE (p. 340), in supposing that *Heliopora* is a tubicolous annelid. *Heliopora* is *not* a tubicolous annelid, nor does it belong to the "Hydrozoic division of the Cœlenterata," but it is, without a shadow of doubt, as Moseley described it to be, an Alcyonarian.

When I was preparing my paper on the "Siphonoglyphe in the stomodæum of Alcyonarians" in 1883, Prof. Moseley kindly placed at my disposal his preparations of *Heliopora*, and I was able then fully to confirm his conclusions as to the Alcyonarian nature of this interesting coral.

During my visits to the coral reefs on the coasts of North Celebes and the adjacent islands, I came across many large and beautiful specimens of *Heliopora*, some of which I carefully preserved for further investigation at home. I never found the polyps fully expanded with the eight pinnate tentacles standing out from the disk like the petals of a flower, but in the few instances when I saw the polyps protruded ⅛ inch or thereabouts from the surface of the coral the tentacles were partially withdrawn, so that their characteristic features were hidden.

Since my return from Celebes I have made a large number of sections of the material I brought back with me with a view to the publication of a short paper on some further details of its anatomy, and I have recently been able to supplement this by a series of preparations I have made from the excellent material given to me by Prof. Haddon, who found *Heliopora* in abundance in Torres Straits.

I will not venture, in the present state of my investigation, to state my opinion as to the position that *Heliopora* should occupy in the group to which it undoubtedly belongs; I merely wish to call the attention of the readers of NATURE to the fact that its Alcyonarian characters are beyond dispute.

Downing College, August 9. SYDNEY J. HICKSON.

Meteors.

LAST night, between 11.12 and 11.52, I and another observer saw altogether eighty-three meteors, eighty of which were Perseids. Some of them were very brilliant, especially those near the neighbourhood of Aquila.

The remaining three meteors had different paths, one having a direction exactly opposite to that of the Perseids.

The other observer was watching the radiant point and the region around it, while I observed the south-west quadrant.

More observations would have been made, but were interrupted by clouds. W. J. LOCKYER.

Observatory House, Westgate-on-Sea, August 12.

A LIQUID COMPOUND OF NICKEL AND CARBON MONOXIDE.

IN the August number of the Journal of the Chemical Society a full account is given of the remarkable new compound described by Mr. Mond, in conjunction with Drs. Langer and Quincke, at the last meeting of the Chemical Society. The following is an outline of the main facts described in their communication.

Carbon monoxide is found to be affected in a very curious manner when passed over finely divided metallic nickel heated to a temperature of 350°–450° C. The metal becomes converted into a black amorphous powder containing nickel and carbon, the carbon monoxide becoming at the same time changed into the dioxide owing to the loss of carbon. A comparatively small amount of nickel is capable of decomposing a very large quantity of carbon monoxide, and at the commencement of the operation the gas may be passed over at a very rapid rate without any escaping decomposition. As the operation continues, the change becomes less and less complete, but even after numerous repetitions of the experiment carbonic anhydride continues to be formed. The solid product of the reaction appears to vary in composition somewhat widely according to the temperature and the time during which the operation is carried on. The highest proportion of carbon found was 85 per cent. Some time ago MM. Gautier and Hallopeau obtained a similar product, containing 80 per cent. of carbon, by the action of carbon bisulphide upon metallic nickel. The nickel is only partially removed by acids, for even after repeated extraction the whole of the nickel is not found in solution.

When this black substance was allowed to cool in the current of carbon monoxide another change was found to occur, with production of some volatile substance, whose vapour rendered a non-luminous Bunsen gas flame placed in its path highly luminous. Further, on heating a portion of the tube near the exit a mirror of metallic nickel was obtained mixed with a little carbon. Evidently a gaseous substance containing nickel was contained in the issuing gas, a circumstance of considerable importance in view of the non-volatility of the ordinary known compounds of nickel. Experiments were then made with the idea of obtaining larger quantities of the new substance and isolating it from the other gaseous products. It was eventually found that when finely divided nickel, obtained by reducing nickel oxide in a current of hydrogen at a temperature of about 400°, is allowed to cool in a slow stream of carbonic oxide, the latter gas is very readily absorbed as soon as the temperature has fallen to about 100°. If the current of carbon monoxide is continued, or if that gas is replaced by an inert gas, such as carbon dioxide, nitrogen, or even hydrogen or air, the issuing gas carries away with it large quantities of the new nickel-containing vapour. After about an hour the quantity of this vapour evolved becomes less, and finally its evolution ceases. The property of the nickel to produce it is restored by heating it to 400° again and allowing once more to cool; indeed, up to a certain limit it forms the compound more abundantly after repeated use. If the issuing gas is collected and heated to 150°, its volume is found to largely increase, nickel more or less contaminated with carbon being deposited. At a temperature of 180° the nickel deposited was found to be quite free from carbon.

The new volatile compound was eventually isolated by leading the mixed issuing gases through condensers placed in a freezing mixture of ice and salt, in which the vapours condensed to a *colourless* mobile liquid of very high refractive power.

The final arrangement adopted for the preparation of the liquid is as follows. A quantity of nickel oxide is placed in a combustion tube, and reduced at about 400° by the passage of a current of hydrogen gas. The tube and contents are then cooled down to about 30°, and pure dry carbon monoxide instead of hydrogen passed through the tube without further heating it. The issuing gas is caused to pass through a Y tube surrounded by ice and salt. The lower end of the Y tube projects through the vessel containing the freezing mixture into a small flask in which the liquid collects. The gas leaving the Y tube still retains about 5 per cent. of the new body, and is therefore collected, dried, and again passed over the nickel until no more liquid condenses. The tube containing the nickel is then re-heated to 400° in a slow current of hydrogen, again cooled, and the operation recommenced. In this manner it is easy to obtain ten to fifteen grams of the liquid in each operation.

The liquid boils at 43° under a pressure of 751 mm. Its specific gravity is 1·3185 at 17°. At −25° it solidifies to a mass of needle-shaped crystals. The liquid is soluble in alcohol, and even more readily in benzene and chloroform. It is perfectly indifferent to dilute acids and alkalies, and is not attacked by concentrated hydrochloric acid. Strong nitric acid oxidizes it readily. As regards its composition, the nickel was estimated by weighing the nickel deposited on passing repeatedly through a heated tube, and the carbon by passing the vapour mixed with air over copper oxide, and absorbing and weighing the carbon dioxide produced. The following numbers were obtained:—

	I.		II.		Calculated for $Ni(CO)_4$.
Nickel ...	33·35	...	33·37	...	34·34
CO ...	66·60	...	65·99	...	65·66

Its composition, therefore, appears to be represented by the formula $Ni(CO)_4$. Its vapour density, the first density determination of a nickel compound, was determined by Victor Meyer's method at 50°. The value obtained was 6·01. $Ni(CO)_4$ corresponds to the density 5·9. At 60° the vapour was found to explode with considerable violence.

Vapour of nickel-carbon oxide, as its discoverers term it, reduces an ammoniacal solution of cuprous chloride, first decolorizing it and subsequently precipitating from it metallic copper. It also precipitates metallic silver from ammoniacal solutions of silver chloride. Chlorine decomposes it with production of nickelous chloride, $NiCl_2$, and carbon oxychloride, $COCl_2$. Bromine reacts in a precisely similar manner. The electric spark decomposes it slowly into nickel and carbon monoxide.

Experiments have also been made to ascertain the possibility or otherwise of preparing a similar compound of cobalt and carbon monoxide. It was found, however, that cobalt does not form such a compound; indeed, it is quite possible to separate nickel from cobalt by reacting with carbon monoxide in the above manner, the nickel only being removed. The metallic mirrors obtained by the decomposition of nickel-carbon oxide by heat were found to consist of unusually pure nickel, containing no traces of cobalt. They consisted of a grey metallic powder of specific gravity 8·2834 at 15°·4.

It became interesting, therefore, to ascertain the atomic weight of this pure nickel, especially in view of the recent work of Drs. Krüss and Schmidt. Accordingly, a series of three determinations were made, with the following results:—If O = 16, Ni = 58·58, 58·64, and 58·52. These numbers are sufficiently close to the value 58·74, long ago obtained by Dr. Russell, to justify the conclusion that nickel, as we have known it, is indeed a simple substance, whose atomic weight lies very near to the figure hitherto accepted—a conclusion which is further supported by the determination of the vapour density of this remarkable new compound, nickel-carbon oxide.

A. E. TUTTON.

BRITISH MUSEUM NATURAL HISTORY PUBLICATIONS.[1]

THE present Part (IV.) concludes Mr. Lydekker's "Catalogue of the Fossil Reptilia and Amphibia in the British Museum (Natural History)," the four volumes making together a work of 1247 pages. In Part I. the author records the Ornithosauria, the Crocodilia, the Dinosauria, the Squamata, the Rhynchocephalia, and the Proterosauria; Part II. contains the Ichthyopterygia and Sauropterygia; Part III. embraces the Chelonia; and Part IV. the anomalous group of the Placodontia, the Anomodontia, and the class Amphibia,

FIG. 1.—*Cyamodus* (*Placodus*) *laticeps*, Owen. A, palatal aspect; B, frontal aspect of cranium; from the Muschelkalk of Baireuth, Germany.

including the Ecaudata, the Caudata, and the Labyrinthodontia, with supplementary notes and additions to the preceding orders. The earlier parts having been already noticed in NATURE, we shall confine our attention to Part IV.

Amongst the rare remains of Reptilia met with in the Muschelkalk of Baireuth, Bavaria, none are of more interest than those belonging to the anomalous group of the Placodontia, the ordinal position of which is still uncertain. The skull and teeth of one of these reptiles

[1] "Catalogue of the Fossil Reptilia and Amphibia in the British Museum (Natural History), Cromwell Road, S.W." Part IV., containing the Orders Anomodontia, Ecaudata, Caudata, and Labyrinthodontia; and Supplement. By Richard Lydekker, B.A., F.G.S., &c. Pp. 295 and xxiv. With Index to the entire Work. Illustrated by 66 Woodcuts. (London: Printed by Order of the Trustees: and sold by Longmans and Co.; B. Quaritch; Asher and Co.; Kegan Paul, Trench, Trübner, and Co., &c., 1890.)

was originally referred by Count Münster, and afterwards by Agassiz, to the class of fishes, under the genus *Placodus;* but more perfect specimens enabled Prof. Owen, in 1858, to show that this animal was really a reptile which probably fed upon shell-bearing mollusks and used its flat, broad, palate-like teeth, so thickly-coated with enamel, for pounding and crushing their shells (see Phil. Trans., 1858, p. 169).

Two genera, *Placodus* and *Cyamodus*, are referred to this group, at present known only by the skull and teeth, no vertebræ or bones of the pectoral or pelvic girdles, or limbs, having been as yet discovered. Owen originally referred this singular form to the Sauropterygia, but subsequently he regarded it as belonging to the Anomodontia, in which order Seeley also places the Placodontia. The present author, however, assigns the Placodonts to no ordinal position, a course which, we think, is to be regretted. If not Anomodont reptiles, why not give them the value of an order? Surely they have as good a claim to such a position as *Proterosaurus?*

FIG. 2.—Left lateral aspect of skull of *Galesaurus planiceps*, Owen; from the Karoo beds (Triassic), South Africa. (½ nat. size.) *a*, an upper cheek-tooth; *b*, an incisive tooth.

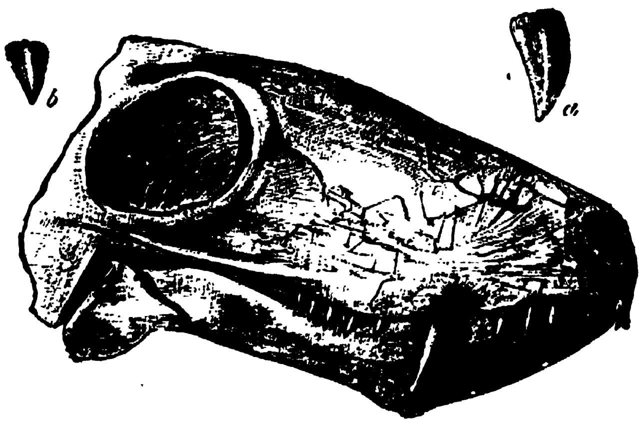


FIG. 3.—Right lateral aspect of imperfect cranium of *Ælurosaurus felinus* Owen; from the Karoo beds (Triassic), Beaufort West, South Africa. (⅔ nat. size.) *a*, upper incisive tooth; *b*, upper cheek-tooth, enlarged.

The Anomodontia, which follow next in order, are a truly Triassic group, and have been met with in Russia, India, North America, and in South Africa. It is especially from this last-named region that the British Museum collection has been most largely recruited, the majority of the specimens having been procured by Messrs. A. G. and T. Bain, Dr. Atherstone, and Sir George Grey. Quite recently, Prof. H. G. Seeley, F.R.S. (assisted by the Government Grant Committee of the Royal Society), visited the Cape, where he was most successful in obtaining a large series of reptilian remains, not yet fully worked out, but of which sufficient is already known to justify us in believing it will prove one of the most valuable additions made for years past to our National Museum.

The interest attaching to these South African Triassic rocks (if Triassic they be) lies in the fact that they have yielded evidence of one of the earliest mammals known—*Tritylodon*—represented by a most remarkable although imperfect cranium, with dentition similar to Cope's genus *Polymastodon*, from the Eocene of North America.

In the group of Anomodont reptiles are included several forms having a well-differentiated series of cheek-teeth, canines, and incisors, a character of dentition considered at one time to be peculiar to the Mammalia. Good examples of such dentition may be seen in the skulls of *Galesaurus*, *Ælurosaurus*, *Lycosaurus*, &c.

Another no less singular family, placed in this order, is that of the Dicynodontidæ, in which the surface of the

FIG. 4.—Lateral view of the skull of *Dicynodon lacerticeps*, Owen; from the Karoo series, South Africa.

palate and mandible are without teeth, the skull being provided with a pair of tusk-like maxillary teeth, growing from persistent pulps; the alveolar margins of the jaws being trenchant, and probably encased in a horny beak-like sheath, as in *Hyperodapedon*.

Another remarkable form of Anomodont, from these Reptiliferous beds of South Africa, has been referred to the genus *Pariasaurus* by Owen. In the form of its

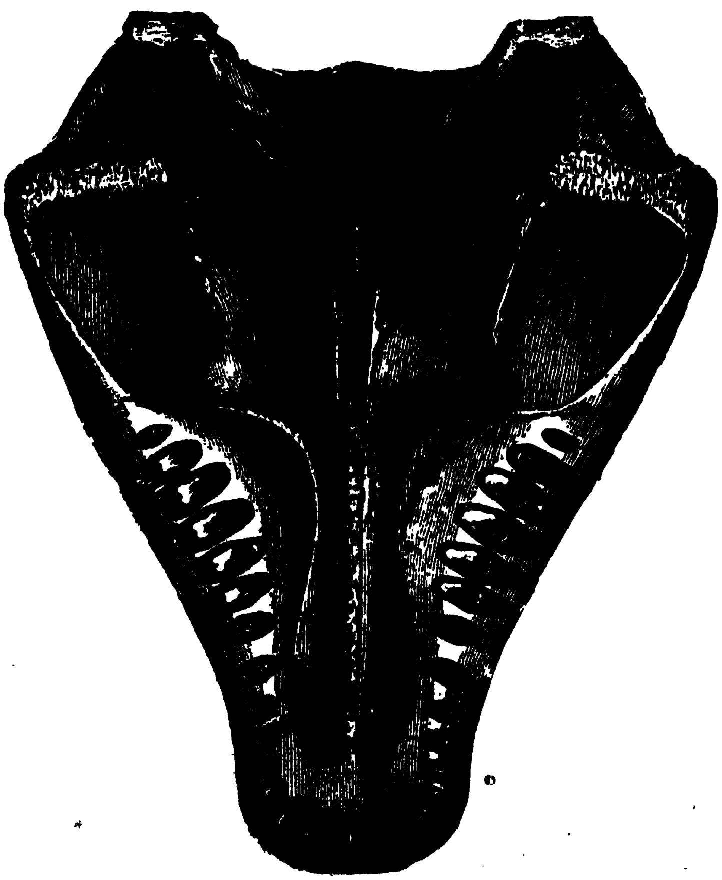

FIG. 5.—Palatal aspect of cranium of *Empedias molaris*, Cope; from the Permian of Texas, North America. (½ nat. size.)

head it is very like a huge Salamander, 8 to 10 feet in length, having a numerous and uniform series of moderately tall marginal teeth in its jaws, with swollen and narrow crowns, ornamented with a few deeply-marked flutings descending from the cutting edge, and with numerous small conical teeth on the palate. The

skull is deeply channelled on its surface, as in the Crocodilia and the Labyrinthodontia.

From the flattened wearing away of the crowns of the teeth, Prof. Owen has suggested it was a vegetable-feeding reptile. The vertebræ of *Pariasaurus* are notochordal, frequently having intercentra present, and there are not more than two vertebræ united to form the sacrum.

The Permian rocks of Texas have yielded to Prof. Cope a most remarkable genus of Anomodont reptiles, named by its describer *Empedias molaris*. The dentition forms an uninterrupted series without a distinct tusk, the incisors differing but little from the cheek-teeth in form, each tooth having a more or less distinct transverse edge. The teeth are about fifty-six in number.

The genus *Naosaurus*, also from the Trias of Texas, makes us acquainted with a very curious reptile, in which the neural spines of the vertebræ are of most enormous height, and each spine has often as many as six paired horizontal processes at intervals produced from its sides.

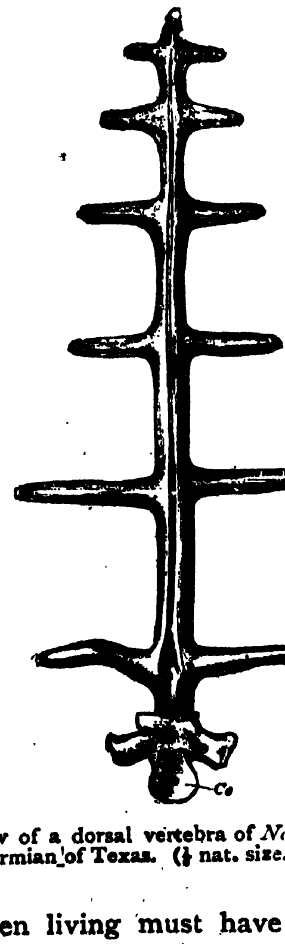

FIG. 6.—Anterior view of a dorsal vertebra of *Naosaurus claviger*, Cope; from the Permian of Texas. (¼ nat. size.) *Ce*, centrum.

This reptile when living must have had an enormous dorsal crest, like some monstrous newt, rising from its back, but it is difficult to conceive any advantage which its owner could possibly derive from such an unwieldy appendage.

Turning to the Amphibia, one cannot fail to be struck by the similarity in the form of the cranium, and its external ornamentation, in the Labyrinthodontia and the Crocodilia. The body is also long, usually lacertiform, and the feet pentadactyle; a bony thoracic buckler and bony scutes are frequently present on the ventral aspect of the body. Doubtless these old Triassic reptiles were ancestrally related to the later Crocodilia, as well as to other and higher forms of Vertebrata.

Teeth in the Labyrinthodonts are usually present on the palatines and vomers, and more rarely on the pterygoids; and there is very generally an ossified sclerotic ring to the orbit. The vertebræ exhibit considerable variation in condition, being amphicœlous, and fully ossified in some instances, or with a notochordal canal, or with large intercentra and the centra represented by paired lateral pieces (pleurocentra) in others.

The parietal foramen is always present in the cranium, and in the Mastodonsauridæ the occipital condyles are well ossified.

The Trias of Würtemberg has yielded the finest known examples of these Labyrinthodont reptiles, quite recently described and figured by Dr. Fraas; but the most complete skeletal remains of Amphibia have been obtained from the Gaskohle (Lower Permian) of Bohemia by Dr. Anton Fritsch, of Prague; others from Germany by Prof. Credner, of Leipzig; and by Prof. Gaudry from the Lower Permian of Autun. The best examples in the collection are those of *Archægosaurus* from the Lower Permian of Saarbrücken, and of *Loxomma* from the Coal-measures of Coalbrookdale and Scotland.

To the Ecaudata (frogs and toads) little interest attaches in a palæontological sense, as no tailless forms of Amphibia are known earlier than the Miocene period; but good examples of these have been obtained from the Brown-Coal of Rott, near Bonn, and from the Fresh-water Tertiary Limestone of Oeningen, which also yields the remains of *Cryptobranchus scheuchzeri*, closely related to the giant salamander now living in the fresh-waters of Japan.

Contrasting for a moment the MAMMALIA with the REPTILIA, while many genera of the former, such as *Dinotherium*, *Mastodon*, *Machairodus*, *Phenacodus*, *Palæotherium*, *Anthracotherium*, *Taxodon*, *Sivatherium*, *Dinoceras*, and others, have died out, *eight entire orders* of REPTILIA and AMPHIBIA, embracing more than 200 genera, have all disappeared. This is the more readily understood when we consider the comparative periods of geological time during which the Mammalia and Reptilia have respectively flourished; for whilst it is true that the earliest known forms of Mammalia made their appearance as far back as the termination of the Triassic period, yet during the whole of the succeeding Jurassic and Cretaceous periods their numbers were few and their forms quite insignificant; and it is not until we arrive at Eocene times that the Mammalia commence to occupy anything like a prominent position in the animal kingdom. On the other hand, the Amphibia began to be abundant as early as the Coal period; and the Reptilia (ushered in by *Proterosaurus*) in the Permian attained a maximum development both in size and numbers in the Lias and Oolites, whilst the Mammalia were yet only in the incipient stage of their development.

Great credit is due to Mr. Lydekker for the manner in which he has performed the task of preparing these Catalogues for the National Collection, a work which will doubtless prove of extreme value to students of comparative anatomy and to workers at a distance who desire to know what objects in any particular family or genus the Museum possesses.

We could wish that greater distinctness had been given in printing these Catalogues to the important fact of particular specimens being the ones which are known as "types," and which are the actual ones that have been figured and described; where this is mentioned it does not catch the eye at once, as it should do. We would advocate the placing of such information in a separate line; and, if possible, they should be marked prominently by the use of *special type*. Perhaps the word "type" or "figd." could be inserted in black letter and begin a separate line.

Again, the formation and locality are hardly prominent enough, and under each genus we would like to see the "range in time" and also the "geographical distribution" given as a separate paragraph.

We hope this series of Catalogues, so helpful to all real workers, may be continued and completed for every group in the Geological Department. The Trustees could not perform a more useful service to science than by urging forward the issue of these works in every Department of the Museum.

THE AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE third annual meeting of this Association will be held, as we stated last week, at Christchurch, New Zealand. On January 15, the President-Elect, Sir James Hector, F.R.S., will hold a reception in the grounds of Christ's College, and the first general meeting will take place in the evening, when Baron F. von Mueller, F.R.S., will resign the chair, and an address will be delivered by his successor.

The Council of the Australasian Association invite the members of the British Association to attend this meeting, and a circular relating to the matter, signed by Profs. A. Liversidge, F.R.S., W. Baldwin Spencer, and F. W. Hutton, the general secretaries, will be distributed at the Leeds meeting. The cheapest way of reaching New Zealand is by the direct steamers which leave Plymouth every fortnight for Wellington. These steamers call at Teneriffe, Cape Town, and Hobart on their way out, and at Rio de Janeiro and Teneriffe on their way back. In the circular to which we have referred, it is stated that return tickets will be issued to members of the British Association proceeding to New Zealand to attend the Christchurch meeting for £84, which is 20 per cent. below the ordinary return fares. These tickets will be issued by the New Zealand Shipping Company and by the Shaw, Savill, and Albion Company, and holders may return by either line. In addition to this advantage, members of the British Association will be allowed to travel over the New Zealand Government railways (1770 miles) at half fares during January and February.

Visits to places of interest in the immediate neighbourhood of Christchurch will be made during the meeting. After the meeting is over, excursions will be made to the West Coast Sounds; to the top of Ruapehu; and, if possible, to the Upper Rakaia. The trip to the top of Ruapehu will start from Napier, and will be accompanied by Mr. H. Hill. The trip to the Sounds will start from Port Chalmers, and will be accompanied by Prof. Hutton.

Members of the British Association have thus a splendid chance of visiting New Zealand, and of seeing for themselves what is being done in science by our kinsfolk in Australasia; and no doubt a good many will avail themselves of the opportunity. Those who decide to accept the invitation are requested to notify their intention, as well as the name of the steamer by which they propose to go, to Prof. F. W. Hutton, the general secretary in Christchurch, in order that arrangements may be made for their reception. The following steamers will leave Plymouth in time for the meeting:—

Company.	Steamer.	Leave Plymouth.	Arrive at New Zealand.
N.Z. Shipping Co.	S.S. *Kaikoura.*	Nov. 15, 1890	Dec. 28, 1890
Shaw, Savill, and Albion Co.	S.S. *Doric.*	Nov. 29, 1890	Jan. 11, 1891

Members going by the *Kaikoura* could visit the Hot Springs district of the North Island before attending the meeting.

NOTES.

NOTHING of scientific value can be extracted from the ghastly descriptions of the recent electric execution. These graphic horrors are too evidently manufactured for sensational or political purposes to be trusted, even had the writers been spectators of the scene. But we may at least gather from them that an entire absence of physiological knowledge, and a very scant acquaintance with elementary physical principles, were exhibited alike by the contrivers of the operation and by the actual operators. With our present physiological knowledge, electric *currents*, whether steady, interrupted, or alternating, are not qualified primarily to produce death, but torture—which, of course, may lead ultimately to death. They have been recommended, in the interests of humanity, as efficient and (if the expression be permitted) healthy substitutes for the "cat." But Nature's own operations, in a thunderstorm, suggest the true substitute for the axe or the cord, viz. the discharge of a condenser of sufficient capacity, charged with so-called "statical" electricity.

THE French Association for the Advancement of Science has been holding its annual meeting at Limoges. The meeting began on August 7, and will come to an end to-day. M. A. Cornu, the President, chose as the subject for his address "the part played by physics in the recent progress of the sciences."

A CONSIDERABLE impetus to scientific study ought to be given by the science scholarships which the Royal Commission for the Exhibition of 1851 is about to establish. They amount in the aggregate to £5000 a year, and are to be used for the benefit of English provincial colleges, and of colleges in Wales, Scotland, Ireland, and the colonies. In accordance with the recommendations of a scientific committee, each of the scholarships will be £150 a year in value, and will be tenable for two years—in rare cases for three; and they are to be restricted to those branches of science (such as physics, mechanics, and chemistry), the extension of which is specially important for our national industries. A series of seventeen scholarships will be allotted to various institutions annually. The first allotment, as the Commissioners explain in a paper they have issued, is to be considered experimental and temporary. "The selection now made of institutions to which nominations are offered will be subject to modification in the future, having regard not only to the manner in which the nominations are exercised, but also to the claims of other universities and colleges which may from time to time be brought under the consideration of the Commissioners."

THE Reale Istituto di Scienze e Lettere of Milan offers prizes as follows:—(1) A historico-critical investigation of works on the variations of climate in geological times (with estimation of hypotheses as to the causes of those changes). Prize, 1200 lire (the lira equals 9½*d.*). (2) A monography of the Protista of spring water in Milan. Cagnola Prize of 2500 lire, and a gold medal of 500 lire. (3) Elucidation, by personal observations, of some points in the physiology of the nervous system, especially the brain. Fossati Prize of 2000 lire. (4) Elucidation of the physiology, or the macro- or microscopic anatomy, of the brain. Fossati Prize of 2000 lire. (5) Draper's theory of the progressive development of the light-rays of a body whose temperature is gradually raised having been attacked by Prof. Weber, a thorough investigation of the phenomena is desired, so as to establish their laws, to exclusion of the ordinary influence of the observer on the meaning of the phenomena. Secco-Commeno Prize of 864 lire. Papers to be written in Italian, French, or Latin, and sent in, with motto, to the Secretary, Palazzo di Brera, Milan. The dates are—for No. 1, April 30, 1891; for Nos. 2 and 3, May 1, 1891; for No. 4, April 30, 1892; and for No. 5, May 1, 1893.

THE Berlin Academy of Sciences has recently granted £60 (each) to Prof. Dames, of the Mineralogical Museum, for a geological investigation of Dalecarlia and the island of Gotland; to Prof. Urban, of the Botanical Garden, for a visit to Paris, to study the specimens of West Indian flora there; and to Dr. Rinne, for study of the Central German basalts. Further, £75 has been granted to Prof. Nussbaum for publication of his studies on Californian Cirrhipedia, and £27 for printing of Dr. Schumann's researches on the union of races. £75 is granted to the Anatomical Society, to further the publication of Prof. His's uniform anatomical terminology.

DR. ST. GEORGE MIVART, F.R.S., has been appointed Professor of the Philosophy of Natural History at the University of Louvain. The professorship is one of those included in the Faculty of Philosophy and Letters.

THIS week the Royal Archæological Institute has been holding its annual Congress at Gloucester. The first meeting took place on Monday, when the chair was taken by Sir John Dorington, in succession to Lord Percy. In his presidential address, Sir John described the neighbourhood of Gleva as it was under Roman civilization in contrast with its later condition in the time of the Saxon invasion.

ON Tuesday the Royal Horticultural Society held a meeting and show in the Drill Hall, and certificates were distributed by the Committee. A paper by Mr. Badger, on fruit-drying by evaporation, as practised in America, was read by Mr. Wilkes, the Secretary. Little fruit, it is said, will be preserved in England this year by the processes described, a worse season generally for plums and apples having seldom been known.

ON Monday the Fellows of the Royal Botanic Society held their fifty-first anniversary meeting. The Council, in their report, congratulated the Fellows upon the firm position held by the Society in the year of its jubilee, and thanked them for their action in response to which 109 new names were added to the list. The result was a permanent growth of prosperity, as shown by the total subscriptions for the year—£3568—which had not been reached since 1885.

THE *Kew Bulletin* for August opens with some interesting notes on Natal aloes, by Mr. J. Medley Wood, the curator of the Natal Botanic Gardens. There are also sections on Gambia mahogany, Ceylon cacao, chestnut flour, wine production in France, and ramie as food for silkworms. The number closes with a list of the staffs of the Royal Gardens, Kew, and of botanical departments and establishments at home, and in India and the colonies, in correspondence with Kew.

IN the new number of the *Internationales Archiv für Ethnographie* (Band iii., Heft 3), there is an article (in German) by Dr. Richard Andree, of Heidelberg, on the Stone Age of Africa. Dr. J. D. E. Schmeltz contributes a finely-illustrated and valuable study (also in German) of decorated weapons used in the East Indies. There is also a short English paper on Zuñi fetiches, by Dr. H. Ten Kate, of the Hague.

THE Japanese collections of Heinrich von Siebold were lately presented to the Hofmuseum of Vienna. They consist of about 5200 specimens, many of which are of great value. In recognition of the donor's generosity, the Austrian Emperor has raised him to the rank of Freiherr.

IN the museum of the Industrial Society of Mühlhausen, there s an interesting ethnographical collection, including a number of fine American antiquities. The objects are being rearranged by Herr E. Grosse.

A WORK on Hindoo folk-lore has just been issued from the London Printing Press at Lucknow, the author being Rai Bahadur Mal Manucha, chairman of the Fyzabad Municipal Board, and well known in Oudh as a legal practitioner. In the preface he says that while he was enjoying the vacation at Hardwar on the Ganges, it occurred to him that if a few notes on religious beliefs, social customs, superstition and folk-lore, proverbs and sayings, puns, riddles, aphorisms, and other miscellaneous matters in common vogue among the Hindoo community generally, and among the country people especially, were brought together, they would "aid a great deal in throwing light upon the hitherto partially explored regions of the mode of life led by the common people." In a lengthy article on the little book the *Times of India* says the author has gathered together a little of everything that his preface promises. We learn, for instance, that if a person is drowned, struck by lightning, bitten by a snake, or poisoned, or loses his life by any kind of accident, or by suicide, then he goes usually to hell. If he die naturally on a bed or a roof, he becomes a "Bhut," or evil spirit, and with this belief care is taken on the approach of death to move the person carefully on to the floor. The earth is believed to be resting on the horn of a cow and the raised trunks of eight elephants, called "Diggai," or "elephants supporting the regions," and each of the cardinal and sub-cardinal points of the compass has its appropriate guardian. An eclipse is produced by the occasional swallowing up of the sun or moon by the severed head of Ráhu, son of a demon family, who was decapitated by Vishnu for disguising himself as a god and drinking nectar.

IN the thirteenth of his "Res Ligusticæ," recently published, Count Salvadori announces the occurrence of *Cypselus affinis* in Liguria on May 14 last. The Count gives full synonymy of the species, and an interesting account of the species on this its first visit to Europe.

IT has been known for some time that Dr. Loria was engaged in prosecuting zoological researches in the Papuan sub-region, and now two instalments of his collection have been described by Count Salvadori. The localities visited by the Loria expedition have been Pulo Penang, Timor Cupang, Pulo Semau, Port Darwin, and Port Moresby in South-Eastern New Guinea. Three new species have been discovered in the latter locality, and have been named by the author, *Ægotheles loriæ*, *Arses orientalis*, and *Pitta loriæ*, the last-named being the only species collected on the island of Su-a-u, a small islet near South Cape.

PROF. GIGLIOLI has ju-t issued the second part of his "Primo Resoconto dei risultati della inchiesta ornitologica in Italia," the first portion of which we noticed last year. This second instalment is in the form of a goodly octavo volume of nearly seven hundred pages, and is entitled "Avifauna Locale." It consists of reports from the various provinces of Italy, furnished by different observers, with remarks as to the nidification, distribution, and migration of the various species. As .o the value of these local lists there can be no question, and Prof. Giglioli may be trusted to choose men with a thorough knowledge of local ornithology to record the observations. As far as we can judge, Prof. Giglioli has been fortuuate in his coadjutors.

THE problem as to the origin of the nephrite of which the tombstone of Tamerlane, at Samarcand, is made—a question which has interested a good many mineralogists—seems to have been definitely solved by M. Grombchevsky's visit to the nephrite-mines on the Raskem-daria, on the eastern slope of the Pamir. M. Grombchevsky found there a big dyke of nephrite, of extreme hardness, embedded in the rocky banks of the Raskem-daria, which consist in that place of white jadite. The Chinese used to extract the nephrite by lighting great fires on the rock, and afterwards throwing water on it when it was heated. They stopped these operations in the course of the present century, when the heir to the throne, after having slept in a bed made of Raskem nephrite, fell ill. A large piece of the stone, so much liked by the Chinese, which was on its way to Peking, was put in chains (like Yakoob-Beg's guns, which are still kept in chains at Yanghi-ghissar) and thrown on the road-side at Kutcha, where it remains. After a careful analysis of the samples brought by M. Grombchevsky, Prof. Mushketoff (in the *Isvestia* of the Russian Geographical Society, xxv., 6) comes to the conclusion that the Raskem nephrite and that of Tamerlane's tombstone are identical.

As to the white jadite in which the dark nephrite is embedded on the Raskem-daria, and which was extracted by the Chinese on the Tunga River, it is like the jade obtained in Burmah on the tributaries of the Irawadi, and described in a recent issue of the *Scottish Geographical Magazine*.

SOME curious results have appeared in an examination, by Herren Geisler and Ulitzsch, of school children in the (Saxon) Freiberg district, with reference to growth (*Humboldt*). Twenty-one thousand children (of both sexes) were measured. The boys, up to the eleventh year, were found to be about 0·6 to 0·9 cm. taller than the girls; but they were then overtaken by the girls; and this superiority of the girls continued till the sixteenth year, when the boys again grew more than the girls. This is against Quetelet's opinion, that boys are throughout bigger than girls.

THE Liverpool Geological Society has issued Part II. of the sixth volume of its Proceedings. Among the contents is an address by the President, Mr. H. C. Beasley, on the life of the English Trias. Mr. T. Mellard Reade contributes geological notes on an excursion to Anglesey; a note on a boulder met with in driving a sewer heading in Addison Street, Liverpool; and a note on some mammalian bones found in the blue clay below the peat-and-forest bed at the Alt mouth.

AT the meeting of the Linnean Society of New South Wales on June 25, Mr. Fletcher exhibited one living and several spirit specimens of *Notaden Bennettii*, Gthr., from three different localities—namely, Dandaloo, on the Bogan River (collected by Mr. A. Fletcher), Warren, on the Macquarie (collected by Mr. Thacher), and Narrabri (collected by Mr. Henry Deane). He remarked that though this toad has hitherto been rare in collections, it is at times not uncommon in its native haunts. In two of the localities above named he had been informed that during April and May of this year considerable numbers had appeared, though possibly the recently prevalent floods may have been concerned in bringing them prominently under notice. From what he had seen of living specimens in captivity, the animals were expert burrowers; and from what he had heard as to their avoidance of water, their comparatively sudden appearance, followed shortly afterwards by a noticeable diminution in numbers, he was inclined to think that the species perhaps resembled the American spade-foot toad (*Scaphiopus*) in keeping generally out of sight except during a short breeding period. Mr. Ogilby remarked that Mr. Helms, who is away on a collecting expedition for the Australian Museum, had recently sent down specimens of the same species from Bourke.

SOME habits of crocodiles have been lately described by M. Voeltzkow. Travelling in Wituland, he obtained in January last 79 new-laid eggs of the animal, from a nest which was five or six paces from the bank of the Wagogona, a tributary of the Ooi. The spot had been cleared of plants in a circle of about six paces diameter; apparently by the crocodile having wheeled round several times. Here and there a few branches had been laid, but there was no nest-building proper. The so-called nest lay almost quite open to the sun (only a couple of poor bushes at one part). The eggs lay in four pits, dug in the hard, dry ground, about two feet obliquely down. Including eggs broken in digging out, the total seems to have been 85 to 90. According to the natives, the crocodile, having selected and prepared a spot, makes a pit in it that day, and lays about 20 to 25 eggs in it, which it covers with earth. Next day it makes a second pit, and so on. From the commencement it remains in the nest, and it sleeps there till the hatching of the young, which appear in about two months, when the heavy rain period sets in. The egg-laying occurs only once in the year, about the end of January or beginning of February. The animal, which M. Voeltzkow disturbed, and saw drop into the water, seemed to be the *Crocodilus vulgaris* so common in East Africa.

IN the last official report from Gambia, the Colonial Surgeon has an interesting paragraph on native diseases. The natives of Africa, he says, who are world-renowned for their superstition, attribute all diseases to one of two causes: either they have been "witched," or some enemy has made "greegree" against them. Of the latter there are two forms: (*a*) the "greegree" that is administered to a person, and most usually consists of an infusion made of roots, leaves, or bark from trees supposed to have the desired properties; (*b*) the "greegree" that is prepared against a person. This is done with much ceremony, and the process is accompanied by incantations, recalling the scene of the "witches' cauldron" in "Macbeth." The treatment relied upon for cure, and much practised in the country, is to call in a man who is supposed to be a "doctor," who, after looking at the patient, sits down at his bedside and writes in Arabic characters on a wooden slate a long rigmarole, generally consisting of extracts from the Koran. The slate is then washed, and the dirty infusion is drunk by the patient. As a result of this state of ignorance and superstition, unqualified practice of every description is openly carried on, and drugs and poisons are daily sold by persons who are wholly ignorant of their properties, but who have acquired sufficient influence over ignorant patients to extort money.

THE *Deutsche Seewarte* has just published in a tabular form the results of the meteorological observations made on German and Dutch ships for the ten-degree square, lat. 20°–30° N., long. 30°–40° W., situated in the centre of the North Atlantic. This is, in fact, the eighth such square which has been similarly published in the last few years; the results for each month are grouped in one-degree squares, of which there are one hundred in each ten-degree square, and the observations for any part of such sub-square are so grouped as to be readily available for combination with the materials collected by other institutions. The winds are recorded under 16 points, with additional columns for variable winds, calms, and storms. Other columns include the means of the various data, the duration of rainfall, and remarks of special interest extracted from the logs used in the discussion. The volume contains xxvi. + 193 large quarto pages.

IN the third number of the *Sammlung von Vorträgen und Abhandlungen*, Prof. Foerster, the Director of the Berlin Observatory, has brought together seven lectures delivered by him in recent years to scientific societies and artisan audiences in Berlin and Hamburg, and various papers reprinted from *Himmel und Erde*, the Prussian *Normal Kalender*, and other sources. Four of the lectures have relation to standard time, the universal meridian, and the Washington Conference; others are included in the prediction of earthquakes and meteorological phenomena, luminous night clouds, the red skies which followed the Krakatão eruption, and Karl Braun's cosmogony. In a paper on the zodiacal light, it is held that, although the constitution of the light is still a matter of doubt, the evidence gained by means of the spectroscope and polariscope indicates that it consists not merely of sunlight reflected from bodies of a meteoritic nature, but also of innate light, due, probably, to electrical effects in a gaseous medium. A paper from the *Kalender* for 1891 contains an account of recent work done at Potsdam on the motion of stars in the line of sight, the instruments employed in the investigation being fully described. Prof. Foerster enjoys some renown in Germany as a popular exponent of scientific questions, and numerous reprints of his papers and discourses have appeared.

THE demand for techical education in New South Wales is rapidly increasing both in Sydney and in the principal centres

of population throughout the country. At present there are between 3000 and 4000 students enrolled, as against a total of 2200 this time last year. A tender has been accepted for the erection of a new technical college in Sydney, to cost £19,537, and the building is to be completed by March next.

THE American journal *Bradstreet's* in a recent article describes a school of manual training at Baltimore, which claims to be the pioneer public manual training school, as well as the only absolutely free school of the sort in the world. The school was opened in 1884 with sixty pupils and four instructors; now it has 549 pupils and fifteen instructors. It has had manual training for its chief object. The ordinary work of advanced public school grades is here but a department called the literary department. This is an essential difference from the manual training in so many schools, where it is one feature of many, and not the chief. It is not meant to teach trades, but rather the use of the tools used in all common trades, and the rudiments of mechanical industry. The regular course of the school takes three years, but there is a preparatory course of two years for the benefit of those who could not continue the ordinary public school course. All the students have their daily work in the shops, drawing-rooms, physical laboratory, and literary department. Each class has its own recitation-room, and only leaves it for drawing, shop, and laboratory work. In shop work the classes are limited to twenty-four boys, while in drawing and other studies double that number are instructed at a time. In the first year fifteen weeks are devoted to carpentry, five to wood-turning, and twenty to forging. In the second year fifteen weeks are devoted to pattern-making, five to moulding, fifteen to vise-work, and five to soldering and brazing. In all the shops instruction is given as to the care and use of tools, laying off and designing work, and the composition of the material used. Each class makes some special design for graduation, and the class this year is engaged on a ten horse-power dynamo, thirteen lathes, and a Gordon printing press. The dynamo will be set up, and is expected to furnish electricity enough to light both buildings with incandescent lights. The boys also do all the plating required, and make all repairs on the machinery in use.

THE additions to the Zoological Society's Gardens during the past week include an Ashy-black Macaque (*Macacus ocreatus*) from the East Indies, presented by Mr. W. J. Bosworth; a Two-banded Monitor (*Varanus salvator*) from the East Indies, presented by Captain W. J. Rule; a Wapiti Deer (*Cervus canadensis* ♀) from North America, an Aard Wolf (*Proteles cristatus*) from South Africa, two Patagonian Conures (*Conurus patagonus*) from La Plata, purchased; two Ariel Toucans (*Ramphastos ariel*) from Brazil, received in exchange; a Barbary Wild Sheep (*Ovis tragelaphus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on August 14 = 19h. 33m. 5s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 4510	—	Pale blue.	19 37 45	+14 25
(2) G.C. 4514	—	Greenish-blue.	19 41 56	+50 15
(3) δ Sagittæ...	4	Yellowish-red.	19 42 29	+18 16
(4) β Aquilæ...	4	Yellow.	19 49 54	+ 6 8
(5) δ Aquilæ...	3·4	White.	19 19 54	+ 2 54
(6) 483 Birm.	7	Very red.	18 58 32	− 5 49
(7) S Scorpii	Var.	—	16 11 7	−22 37

Remarks.

(1) This is a small planetary nebula which gives the usual spectrum of three bright lines, in addition to a comparatively distinct continuous spectrum of considerable length. In further observations special attention should be directed to the character of the chief line, and maxima of brightness in the continuous spectrum should be looked for. It is not improbable also that many faint lines may be found with the improved instruments now in use. In the General Catalogue the nebula is thus described: "A planetary nebula; bright; very small; round."

(2) This is one of the so-called "nebulous stars" appearing in ordinary instruments as a star out of focus. The central nucleus gives a continuous spectrum, but the surrounding atmosphere gives a spectrum consisting of three bright lines. It would be a considerable advance in our knowledge if the spectrum of the nucleus could be determined. It may be that we are simply in presence of a star like those of the Pleiades, produced by the intersection of streams of meteorites, or it may be an ordinary case of condensation of a nebula. In the former case the spectrum would probably be that of a hot star, whilst in the latter case it would be one of an early group, possibly consisting of bright lines. Further observations are obviously required. The General Catalogue description is as follows: "A nebulous star; bright; pretty large; round; star of 11th magnitude in the middle."

(3) A bright star, with a well-marked spectrum of Group II. The bands 2, 3, 7, and 8 are strong, and 1, 4, 5 are well seen (Dunér). The usual observations for bright carbon flutings and absorption lines are required.

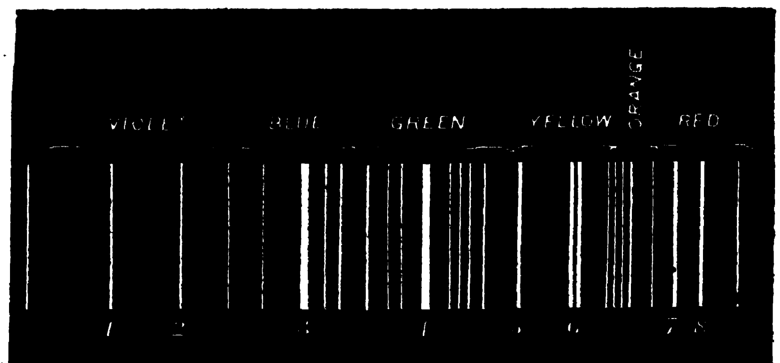
(4) and (5) Gothard states that these are stars of the solar type and of Group IV. respectively, the former being confirmed by Vogel. The usual more detailed observations are required in each case.

(6) This is a comparatively bright star of the rare type of Group VI., and offers a good opportunity for a detailed study of this kind of spectrum. In addition to the three usual carbon bands, it shows the secondary bands 4 and 5 (Dunér). The intensity of band 6 (λ 564), as compared with the other carbon bands, is not recorded by Dunér. The presence or absence of line absorptions should be particularly noted.

(7) The spectrum of this variable has not yet been recorded. According to Gore's catalogue, the period is about 177 days, and the magnitude ranges from 9·1–10·5 at maximum to < 12·5 at minimum. There will be a maximum about August 19.

A. FOWLER.

LIGHTNING SPECTRA.—Mr. W. E. Wood, in the current number of *The Sidereal Messenger*, gives the results of some observations of lightning spectra made on June 22, 1890. The results were obtained with a Browning direct-vision spectroscope of small dispersion, and having no scale, so that the lines mapped in the accompanying diagram are eye estimates.



With respect to the 25 bright lines shown it is remarked, "two moderately bright lines lie in the violet, one heavy bright line in the blue, and which I estimate to be the familiar F line, one brilliant line in the green (the coronal or auroral line?), one brilliant line on the yellowish-green, a double line in the yellow—very brilliant (the sodium line?), a fainter but fairly broad line on the edge of the red, and two very bright lines in the centre of the red, one of which I think is a hydrogen line. The fainter bright lines lie approximately as shown in the diagram. The intense flashes, those which usually do the damage during a storm, gave *exceptionally* faint, continuous spectra, and rarely more than the lines number 3, 4 and 5. Heat-lightning flashes gave the principal bright lines 1 to 8, and the spaces between were occupied by a multitude of finer bright lines. An absorption band in the violet occurred in all *bright* flashes of heat-lightning, and in some cases I saw two

such bands in the red, lying on either side, of the pair 7 and 8. . . . It might be well to state that the line, which I judge to be the auroral line, was in all cases the most noticeable, and especially so in discharges of heat electricity, which seemed to occur in the upper and more rarefied strata of the air."

SOLAR ACTIVITY.—Prof. Tacchini gives the following results of solar observations during the second quarter of this year (*Comptes rendus*, August 4):—

	No. of days of observation.	Relative frequence of spots.	Relative frequence of days without spots.	Comparative area of spots.	Comparative area of faculæ.	No. of groups of spots per day.
April	19	2·08	0·75	1·40	10·40	0·44
May	20	2·55	0·54	2·58	25·83	0·71
June	26	1·35	0·76	0·86	8·10	0·25

A comparison of these figures with those of the first quarter of this year shows that the spots are slowly increasing in magnitude, and that the number of days without spots is diminishing.

The following results have been obtained for the prominence:—

	No. of days of observation.	Mean number.	Mean height.	Mean extent.
			"	"
April	19	1·90	35·2	1·5
May	20	1·55	37·9	0·9
June	26	2·42	27·7	1·3

DENNING'S COMET (*c* 1890).—Dr. A. Berberich has computed the following orbit of the comet discovered by Mr. W. F. Denning at Bristol on the 23rd ult., from observations made at Nice on the 24th and 25th, and at Strasburg on the 27th (*Astronomische Nachrichten*, No. 2982):—

$$T = 1890 \text{ Sept. } 24{\cdot}7573 \text{ Berlin Mean Time.}$$

$$\left.\begin{aligned} \omega &= 158^\circ\ 26'\ 64'' \\ \Omega &= 96\ 35\ 42 \\ \iota &= 99\ 37\ 67 \end{aligned}\right\} \text{Mean Eq. } 1890{\cdot}0.$$

$$\log q = 0{\cdot}12288$$

$$\Delta\lambda \cos\beta = +\ 0'{\cdot}08; \quad \Delta\beta + 0'{\cdot}06.$$

Ephemeris for Berlin Midnight.

1890.	R.A. h. m. s.	Decl. ° '
Aug. 14	15 22 56	+52 45·7
15	23 42	51 22·0
16	24 29	49 57·4
17	25 16	48 32·0
18	26 4	47 5·9
19	26 52	45 39·2
20	27 41	44 11·9
21	28 30	42 44·3

Brightness = 1·82 on August 17, and = 1·95 on August 21, that at discovery being taken as unity.

The comet will pass perihelion about September 25, at a distance of 1·33 the mean distance of the earth from the sun.

From the ephemeris given it will be seen that the comet is between β Boötis and θ Draconis on August 15.

GEOGRAPHICAL NOTES.

THE Russian *Official Messenger* of August 1 gives the following news about the work done by M. Grombchevsky during last spring. On March 13 the expedition left Khotan for Niya. After having passed through the oasis of Keria, the travellers crossed the desert, where they met with a succession of *barkhans* (downs), reaching to the unusual height of 200 feet. From Niya they visited the Sougrak gold-mines, which are worked by nearly 3000 families living in caverns excavated in the loess and conglomerates on the slopes of the hills. Lumps of gold 2 lbs. in weight are sometimes found in these mines. Leaving Niya, the expedition crossed the border-ridge, which consists of several chains—the passes across them attaining heights of from 10,500 to 11,000 feet—and reached Polu, whence it returned to Keria. There M. Grombchevsky received the good news that the expedition would be allowed to continue its work till January 1, 1891, and that £200 had been granted for that purpose; so that M. Grombchevsky made arrangements to start for Rudok, in Tibet, in the first half of May.

THE following telegram about M. Grombchevsky's expedition, dated Marghilan, July 19, has appeared in the Russian *Official Messenger*. The expedition had reached Polu, but had been stopped there by the Chinese authorities, who insisted upon the immediate return of the expedition to Kashgar, and ordered the population to leave their settlements and to camp in the mountains. Brought to despair, M. Grombchevsky spent his last money in bribing some inhabitants, and, without a guide, left Polu in the night of May 17, going further south into the depth of the unexplored wilderness.

THE last number of the *Isvestia* of the Russian Geographical Society is of unusual interest, especially on account of its maps. It contains three reduced photographic copies of the hypsometric map of Russia, by General Tillo, and it is impossible not to admire the distinctness with which the two chief lines of upheaval, the south-west to north-east direction, and the north-west to south-east direction, appear on this map, even amidst the plateaus and the depressions of middle Russia. Another interesting map renders, on a scale of 7 miles to the inch, the surveys of M. Grombchevsky, made during his recent attempts to reach Tibet from the north. The map is accompanied by two letters from the explorer, written in December 1889, at the sources of the Khotan-daria and the Kara-kosh. The same issue contains a letter from the chief of the Tibet expedition, M. Roborovski, dated from Niya, December 11, 1889; a paper on the geodetical surveys in Russia; and a most interesting summary, by M. Kuznetsoff, of his several years' study of the flora of the Caucasus.

IN a communication to the Société de Géographie of Paris, M. G. Marcel, who is one of the librarians of the Bibliothèque Nationale, has given some particulars of Louis Boulanger, an astronomer, geometer, and geographer of the sixteenth century. In 1511 he published at Lyons a work, "Equatorii Cœlestis Motus," of which only one copy is known. It is in the Bibliothèque Mazarin, and is described by M. Marcel as hitherto ignored by bibliographers. In 1514 he brought out a piracy of Muller's "Cosmographiæ Introductio." The globe accompanying this is regarded as the first on which the word "America" is found. Another globe has been found by M. Marcel at the Bibliothèque Nationale, which he regards as having been made by one of the school of Schoener between 1513 and 1518, and on it the then new name of the New World occurs four times. It is therefore either the first or the second cartographic document in which America is mentioned.

THE SCIENTIFIC PRINCIPLES INVOLVED IN MAKING BIG GUNS.[1]

III.

PART III.—WIRE GUN CONSTRUCTION.

AN inspection of Fig. 5 (p. 307), and of the serrated edge of the curve of circumferential tension, *t*, shows that only the inner fibre of each coil is doing its full share of resistance when the gun is fired.

Great economy of material can be effected if we can make all the circumferential fibres take up a full uniform working tension (say of 18 tons per square inch) when the gun is fired; but to secure this condition only approximately, the number of coils would have to be largely increased, and the cost, complication, and time of manufacture of a gun would be enormous.

But, by adopting Mr. J. A. Longridge's plan of strengthening the inner tube A by steel wire, wound round with appropriately varying tension, we are theoretically able to make the curve of circumferential firing tension, *t*, a straight line for a determinate powder pressure; and now all parts of the wire coil are equally strained, and take an equal share in the resistance.

The subject has been investigated theoretically by Mr. Longridge, assisted by Mr. C. H. Brooks, beginning in 1855; and his theories are set forth in papers in the Proceedings of the Institution of Civil Engineers in 1860, 1879, 1884, em-

[1] Continued from p. 334.

bodied in Mr. Longridge's "Treatise on the Application of Wire to the Construction of Ordnance," 1884 (Spon); and again in a paper in 1887, "Further Investigations regarding Wire Gun Construction."

Dr. Woodbridge, of America, claims to have originated the system of strengthening guns with wire, in 1850; but to Mr. Longridge belongs the credit of pointing out the proper mode of winding on the wire with initial tension so adjusted as to make the firing tension of the wire uniform for the maximum proof powder pressure.

Mr. Longridge's principle is applicable not only to engines of destruction, but also to peaceful purposes, such as strengthening the cylinders of hydraulic presses and lifts, and the copper pipes of steam-engines; for which a great, and, we hope, a profitable future is in store.

Returning to the application of the principle to artillery, the great object attained is the notable reduction in weight of the gun—a matter of importance in siege artillery, where the weight of the largest single piece of metal, the gun itself, is limited by the difficulty of transport over bad roads and rough country. By the use of Mr. Longridge's principle, the weight of a howitzer can be reduced from five tons to three and a half—quite sufficient to make all the difference between getting the gun into position, or being compelled to leave it behind.

It is also claimed as an advantage of the wire gun that the construction will be found cheaper and more expeditious, when once the appropriate machinery is erected; and that this machinery need not be nearly so elaborate and expensive as that required with the present system of construction with steel coils shrunk on over each other.

As we have seen in Part II., the appropriate initial state of stress is, in the coil gun, dependent on such delicate fitting as thousandths of an inch, and a slight irregularity in the texture of the metal may be sufficient to completely modify the initial stresses as designed. With the wire gun, on the other hand, the wire can be coiled on to the inner tube from an equal parallel coil of wire, and the appropriate tension given by means of a certain weight running on the free part of the wire, and incidentally testing the strength of the wire. Certain practical difficulties exist in securing the ends of the wire, and in providing for longitudinal strength, which experience will doubtless soon overcome.

Besides Mr. Longridge's "Treatise," the most important is a long article in the *Revue d'Artillerie*, on "Steel Wire Guns," by Lieutenant G. Moch, since published as a separate book, and also translated in the American "Notes on the Construction of Ordnance," No. 48, 1888.

Lieutenant Moch resumes Longridge's and Brooks's calculations, and presents the mathematical work in a more concise and elegant form; he applies his formulas to the design of the wire guns, proposed in 1871 by Captain Schultz, who was unaware of Mr. Longridge's previous work.

We shall attempt here to present the essence of Lieutenant Moch's article in a concise and geometrical form, depending on the method and formulas of Parts I. and II., and illustrated by the design of one of Schultz's guns; referring the reader who wishes to pursue the subject in all its practical details to Moch's original article, and to Longridge's "Treatise."

(44) Taking the cross-section of the gun across the powder-chamber, as composed of the inner tube, A, the wire coil, B,

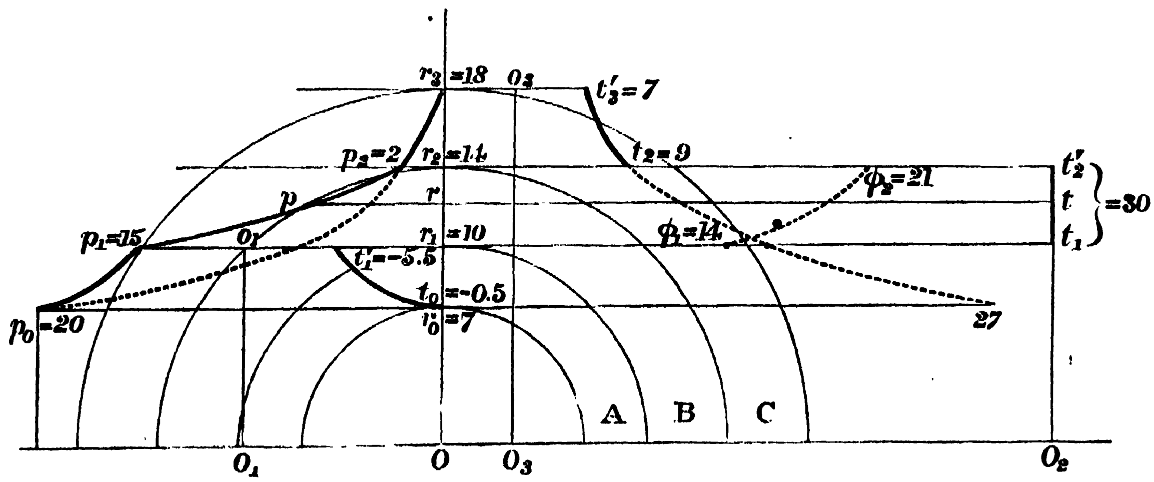


FIG. 9.

and an outer jacket, C, then in the ideal state, the firing stresses will be represented in Fig. 9, where the curve of circumferential tension, $t_1tt'_2$ is a straight line in the wire coil B.

The outer jacket, C, is merely required for protection of the wire from damage by shot, so that it may be supposed fitted over the wire without any appreciable shrinkage; when the gun is at rest, the jacket C will then be in a state of repose free from stress; but when the gun is fired, we may suppose the stresses in C to be the powder-stresses (§ 12, p. 306), on the assumption that the gun behaves as if homogeneous.

We denote by r_0 the internal radius of the tube, by r_1 and r_2 the internal and external radii of the wire coil, and by r_3 the external radius of the jacket, all measured in inches in our units.

Then in the jacket C the curves t'_3t_2 of circumferential tension and r_3p_2 of radial pressure, representing firing stresses, will be Barlow curves, the reflexions of each other in their medial axis O_3o_3.

(45) The continuation of the Barlow curve r_3p_2 in the dotted line up to p_0 will give graphically the powder pressure p_0; but now the curve of firing radial pressure between r_2 and r_0 will be the broken curve $p_2p_1p_0$, of which p_1p_0 in the tube A is the portion of another Barlow curve, but of which p_2p_1 in the coil B is easily seen to be a portion of a hyperbola.

For the curve of firing circumferential tension in the wire being the straight line tO_2, the condition of equilibrium of any cylindrical portion of the wire coil, bounded internally by the radius r, requires that the rectangle r_2t of circumferential resistance should be equal to the rectangle Op − rectangle Op_2; or, in other words,

$$\text{the rectangle } p_2t = \text{rectangle } Op,$$

or

$$\text{the rectangle } O_2p_2 = \text{rectangle } O_2p;$$

which proves that the curve p_2p is a hyperbola, with O_2O and O_2t as asymptotes.

(46) The tangent at any point of this hyperbola—say at p_2—is drawn by joining the point p_2 with points on O_2O or O_2t at double the distance of p_2 from O_2t or O_2O, by a well-known property of the hyperbola.

But to draw the tangent at p_2 of the Barlow curve r_3p_2, we must join p_2 with a point on O_3O at a distance from O_3 treble the distance of p_2 from O_3o_3.

Similarly we can draw at p_1 the tangent to the hyperbola p_2p_1, and the tangent to the Barlow curve p_1p_0, when we know the position of O_1o_1, the axis of this Barlow curve, p_1p_0.

(47) The position of O_1o_1 is fixed by the condition that the curve of circumferential tension in the tube A is the reflexion of the curve p_1p_0 in O_1o_1; and the position of this curve of circumferential tension, $t_0t'_1$, is settled by the condition that the rectangle Op_0 is equal to the sum of the areas of circumferential resistance, bounded by $t_2t'_3$ in the jacket C, by the straight line $t_1t'_2$ in the wire coil B, and by the curve $t_0t'_1$ in the tube A.

(48) It will be noticed in the diagram that, with the numbers given there, the curve $t_0t'_1$ lies to the left of the line r_0r_1, showing

that when the gun is fired the interior of the tube is still in a slight state of compression, so that the circumferential firing stresses of the tube are insignificant pressures, the chief stress being thrown upon the wire.

This theoretical result appears to be of great practical advantage in prolonging the life of the gun, as it is found that the tube of the wire gun has hitherto shown an unexpected vitality; a very gratifying result, when it is considered how short the life of our large guns is, in consequence of the erosion of the bore.

An empirical formula, $N = 2400 \div c - 50$, given by General Maitland (Proc. I.C.E., vol. lxxxix. p. 205) for the life of a gun, where c denotes the calibre in inches, and N the number of full charges that can be fired before the gun requires relining, will illustrate forcibly the comparative longevity of large and small guns: thus, if $c = 16$, $N = 100$; if $c = 12$, $N = 150$; but if $c = 0{\cdot}3$, as in the new magazine rifle, $N = 7950$.

We have now determined graphically the firing stresses in the wire gun, where the powder pressure, p_0, is exactly adjusted, so as to produce uniform t in the wire; a less powder pressure would obviously strain the inner fibres less, and less than the outer fibres; *vice versâ*, a powder pressure greater than p_0.

(49) But now the gun-maker has to determine the initial stresses in his gun from the above state of firing stress, by the operation of stripping off the powder stresses, assuming the gun to behave as if homogeneous.

As a first consequence, the initial stresses in the jacket C will be reduced to zero, as they should be; because we have supposed the jacket C slipped on with merely a mechanical fit.

Secondly, in the wire coil B, the state of initial circumferential tension will be obtained by subtracting the ordinates of the prolongation of the Barlow curve t'_3t_2 from the ordinates of the straight line t'_2t_1; whence we obtain the symmetrical Barlow curve $\phi_2\phi_1$, by reflexion of the Barlow curve $t'_3t_2 \ldots$, produced.

The curve of radial pressure $r_2\varpi_1$ in the wire coil B, obtained by subtracting the ordinates of the Barlow curve p_2p_0 from the hyperbola p_2p_1, is now easily plotted, but is of a more complicated analytical character.

Finally, we come to the state of initial stress in the tube A, obtained also by stripping off the powder stresses from the firing stresses; and consisting of the curve of initial radial pressure ϖ_1r_0, a Barlow curve, and its reflexion, $\tau_1\tau_0$, the curve of circumferential pressure in the tube A; the position of $\tau_1\tau_0$ being settled so as to make the area $r_1\tau_1\tau_0r_0$ equal to the area $r_1\phi_1\phi_2r_2$; and now the state of initial stress is represented in Fig. 10.

(50) We notice that τ_0 is considerable, and may with imperfect design become dangerously near the crushing pressure of the material of the tube A; practically, however, the great crushing pressure τ_0 is considered advantageous, as tending to improve the resisting power of the material against the great enemy, erosion.

In the Severn tunnel, as a different exemplification of these principles, the crushing effect in the brick tube, due to the head of water of the land springs, was not allowed for sufficiently; if the land water around the tunnel is not kept down by pumping, the head of water soon becomes sufficient to cause the bricks on the interior of the tunnel to crush and splinter; and until the interior is strengthened considerably with steel or cast-iron curbs, the expense of pumping cannot be avoided.

(51) There is considerable divergence of opinion as to the

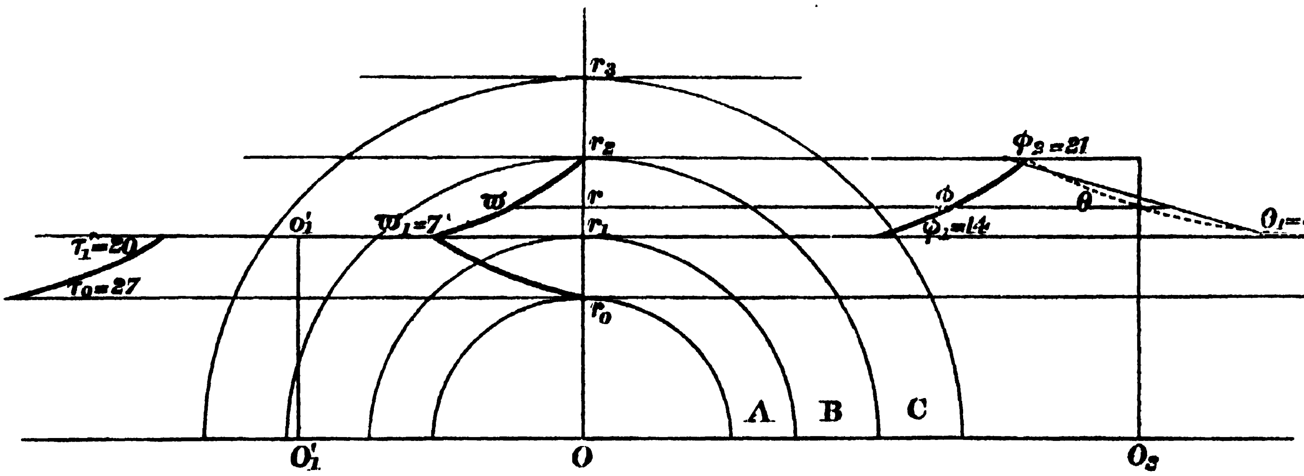

FIG. 10.

proportions to be given to the tube A and the wire coil B; Longridge preferring a comparatively thin tube, A, of some softer material, like cast-iron, while Schultz made his tube of steel, and considerably thicker in proportion, with the advantage of throwing the longitudinal strength into the tube.

As the theory is considerably simplified if we take the tube A and the wire of the coil B of the same elasticity, we shall make Fig. 9 represent the design of one of the Schultz guns, as described by Moch, altering the dimensions and stresses to round numbers in inches and tons.

Now Figs. 9 and 10 represent the section across the chamber of the Schultz 34-centimetre ($13\frac{1}{2}$-inch) gun, in which we have made $r_0 = 7$, $r_1 = 10$, $r_2 = 14$, $r_3 = 18$, in inches, to the nearest integer.

(52) We assume that, under a powder-pressure, p_0, of 20 tons on the square inch, the wire coil is under a uniform circumferential tension of 30 tons on the square inch; a very moderate estimate for what steel wire is capable of sustaining, as 60 would not be excessive.

Numerical calculation by means of the formulas of Part I. gives the following values of the stresses, in round numbers:—$p_2 = 2$, $p_1 = 15$; $t'_3 = 7$, $t_2 = 9$, $t'_2 = t_1 = 30$, whence $\phi_2 = 21$, $\phi_1 = 14$; $t'_1 = -5{\cdot}5$, $t_0 = -0{\cdot}5$, all in tons per square inch.

In Fig. 10 the initial stresses are represented; and we find, as before, $\phi_2 = 21$, $\phi_1 = 14$, $\varpi_1 = 7$, $\tau'_1 = 20$, $\tau_0 = 27$, while the initial stresses in the jacket C are *nil*.

(53) There still remains an important practical detail to be settled theoretically—the formula for the varying tension with which the wire must be wound on the tube A, in order that when the coil is complete the curve of initial tension of the wire should become finally $\phi_1\phi_2$.

The formula has been investigated in all its generality by Mr. Brooks in Longridge's "Treatise," but we shall follow Moch in his article in considering the very much simplified case of uniform modulus of elasticity.

As we have already used the word *initial* to distinguish the stresses in a gun in a state of repose when finished, we shall call the varying tension with which the wire is wound on the gun the *winding tension*, and denote it by θ, in tons per square inch.

(54) Now, to determine θ for any radius, r, of the coil B, Moch assumes that the winding tension of the wire is equal to the initial tension, ϕ, increased by the circumferential tension (pressure) due to the initial radial pressure, ϖ, at the radius r, acting on the partly finished tube and coil between the radii r_0 and r; and thus

$$\theta = \phi + \varpi\frac{r^2 + r_0^2}{r^2 - r_0^2}.$$

In other words, it is assumed that the tension of repose, ϕ, is less than the winding tension, θ, by the amount due to the pressure ϖ at a radius r, and zero pressure at the radius r_0, treating the material as homogeneous.

Now, by the formulas of § 7 (p. 305),

$$\phi = t - p_0 \frac{r^{-2} + r_3^{-2}}{r_0^{-2} - r_3^{-2}},$$

$$\varpi = p - p_0 \frac{r^{-2} - r_3^{-2}}{r_0^{-2} - r_3^{-2}}$$

$$= (p_2 + t)r_2 r^{-1} - t - p_0 \frac{r^{-2} - r_3^{-2}}{r_0^{-2} - r_3^{-2}},$$

where

$$p_2 = p_0 \frac{r_2^{-2} - r_3^{-2}}{r_0^{-2} - r_3^{-2}},$$

so that

$$\varpi = t(r_2 - r)/r - p_0 \frac{r^{-2} - r_2^{-2}}{r_0^{-2} - r_3^{-2}};$$

and the expression for the winding tension, θ, finally reduces to the form—

$$\theta = \mathrm{A} + \frac{\mathrm{L}}{r} + \frac{\mathrm{M}}{r - r_0} + \frac{\mathrm{N}}{r + r_0},$$

where

$$\mathrm{A} = \frac{p_0 r_0^2(r_3^2 - r_2^2)}{r_2^2(r_3^2 - r_0^2)} = p_0 \frac{r_2^{-2} - r_3^{-2}}{r_0^{-2} - r_3^{-2}} = p_2,$$

$$\mathrm{L} = - tr_2,$$

$$\mathrm{M} = t(r_2 - r_0) - p_0 r_0 \frac{r_0^{-2} - r_2^{-2}}{r_0^{-2} - r_3^{-2}},$$

$$\mathrm{N} = t(r_2 + r_0) + p_0 r_0 \frac{r_0^{-2} - r_2^{-2}}{r_0^{-2} - r_3^{-2}},$$

after considerable algebraical reduction.

(55) A great simplification is introduced if we put $r_3 = r_2$, equivalent to supposing that the jacket C fits loosely over the coil B, so that the firing stresses do not extend into the jacket C, which, therefore, now contributes nothing to the strength of the gun; and now $\mathrm{A} = 0$, $\mathrm{L} = - tr_2$, $\mathrm{M} = tr_2 - (t + p_0)r_0$, $\mathrm{N} = tr_2 + (t + p_0)r_0$; and we thus obtain the formula (51) of Longridge's "Treatise," or formula (50) of Moch's article.

With the numbers of Fig. 10, we find $\theta_1 = 34$, while obviously we always have $\theta_2 = \phi_2$, as the winding tension of the last layer of wire is the same as the tension in repose.

Having plotted out by points the curve $\theta_1\theta_2$ for the winding tension θ, a curve of the fourth degree, it will be found practically correct enough to replace it by the most approximate straight line; and now in winding the coil, the difference of the tension weights destined for two consecutive layers of wire remains constant.

(56) We have now finished the theory of the wire gun, so far as the circumferential strength is concerned; and for its experimental verification, an interesting article in Note No. 38, on the Construction of Ordnance, "On Winding and Dismantling an Experimental Wire-wound Gun Cylinder," by Lieutenant W. Crozier (Washington, June 1886), may be consulted; and according to recent reports a 10-inch gun has been recently constructed in America by Captain Crozier, on designs based upon his experimental results.

The theory of the longitudinal stresses in the wire gun has not been touched upon, because it is still a point of dispute as to whether the tube alone should provide the longitudinal strength, or whether it should be partly borne by the outside jacket, the wire coil being obviously unable, except in Canet's double coning system, of giving any assistance in this direction.

Mr. Longridge's principle of strengthening a tube with wire, wound with appropriately varying tension, will be found useful in peace and in war: he can claim credit that a gun strengthened on this principle, the 9·2-inch wire gun, was chosen from its great strength to test the extreme range of modern artillery in 1888, with what were called the "Jubilee rounds"; when, with an elevation of about 40°, a range of 21,000 yards, or 12 miles, was attained, the projectile weighing 380 pounds, and the muzzle velocity being about 2360 f.s.

The dimensions in the diagrams have been purposely taken in round numbers, so as not to represent invidiously any particular gun; in some cases, inappropriate stresses have made their appearance; and now it is the art of the gun-designer to modify slightly the dimensions of the parts of his first rough sketch, so as to attain to more uniformity of strength and a better theoretical result.

There is no claim to originality in the theory that has been given above, and we fear that due credit has not always been properly assigned to the right investigator; but the attempt has been made to present the essential points of the theory in as simple a form as possible, with a minimum recourse to algebraical formulas. The subject has been written about so much of late years that the reader is apt to be confused with the variety of notation and treatment; and it is hoped that the graphical method presented here will enable the theorist to present his results to the practical gun-maker in a more intelligible and convincing form.

A. G. GREENHILL.

ON PUTREFACTIVE ORGANISMS.[1]

THE author said his difficulty was to decide in which way to treat his subject. He might summarize the investigations of twenty years, and endeavour to show the original motives which led to their being undertaken, and then contrast this with the new meaning which has been derived from the investigations founded on recent methods and instruments; or, secondly, he might show the results of a series of continuous observations on certain saprophytic organisms placed under increasingly adverse environments, so as to endeavour to discover their behaviour in regard to the great Darwinian law. He inclined to this last as the view of his work that might have the broadest interest to a Society like that he was addressing; but the value of the improvements in recent lenses led him to give the priority to the results so obtained. In the case of larger animals, it was well known that a change of environment produced changes in the organism; but that these changes were hard to follow up, owing to the few generations that come under the notice of the student or observer. But in the case of micro-organisms the generations succeed each other so rapidly that it is easy to follow the changes produced by environment. He could show the effect on certain micro-organisms of a gradual change of temperature, and how in from seven to eight years an organism arose which lived and multiplied at a temperature of 157° F., whose ancestors had lived at a temperature of 65° F., and would have died if exposed to temperatures above 100°. He said there was nothing harder than to carry an audience to a just appreciation of the lower forms of life, but nevertheless he hoped to point out some of the practical results due to the improvements in modern microscopes. If they took a glass of drinking-water and put in it some shreds of fish, or any other organic substance, it soon became turbid and charged with the minutest organisms. To illustrate the number of these organisms, Dr. Dallinger said that visible to the human eye in the heavens there were in all probability with our most powerful modern telescopes 100,000,000 stars; and if they supposed that each of these, like our sun, was attended by eight primary bodies and twenty secondary planets, there would be two thousand eight hundred millions of bodies in space accessible to human research. The same number of these minute organisms to which he had referred would lie in a space equal to one ten-thousandth of a cubic inch. Any such a molecule of even dead matter must arrest the attention of the human mind; but when we remembered that these were complex *vital* forms, they had a significance of a high order, and their inconceivably rapid multiplication would make the mind pause and think. A decomposing mass of matter was a mass of beings endowed with life, and producing definite products. The life of the organism was not even an incidental product, the organisms were there for a purpose. They break up the decomposing organic matter into its elements, and so make it ready again for the purposes of life. Dr. Dallinger went on to describe some of the organisms which he has observed and examined. He said, that if they took some putrescent fluid from different putrefactive material, and mixed them, then put a very minute quantity of sterilized fluid on the microscope slide, and put into this the point of a needle which had been inserted into the mixture of putrefaction, and examined it with a sufficiently powerful microscope, the field of view in the microscope became, as it were, charged with life in an instant. There were many kinds of organisms, and they had many movements. There were rod-shaped organisms, spiral forms, a perfect oval form with two flagella, or whips. Another would be like the calyx of a papilionaceous flower, and have four flagella. Another would have a delicate egg-shape, and another be shaped like a double convex lens, and move with a beautiful wave motion. The fluid speck seen under the microscope was densely peopled. What were these organisms, and what their functions amid the denizens

[1] Abstract of an Address delivered before the Bristol Naturalists' Society, by the Rev. W. H. Dallinger, F.R.S.

of earth? They were extremely small, and the largest of them so small that one hundred millions could be packed within a cube whose side was equal to the diameter of a coarse human hair, and there were from ten to twenty less than this. This group were amenable only to the most powerful microscopes. It was known long ago that they carried on putrefaction; now they knew that the process was a fermentation. Dr. Dallinger then went on to contrast ordinary saccharine fermentation, like that of yeast, producing carbonic acid and alcohol, with the fermentation produced by these saprophytic organisms, and showed that both could be prevented by taking care to keep away any of the germs of the fermentation, that both could be arrested by the action of heat, and that both tended to break up the organic matter into simpler forms. In the case of the saprophytes, water and carbonic acid were produced eventually from the decaying mass on which they dwell, and thus by the vital functions of these organisms the chemical elements in the animal body were restored to nature, to become once more part of the protoplasm of living things. There were, however, two things in which these saprophytic ferments were different from ordinary ferments; in the latter a special organism produces a special product, whereas in the former there was no such definite product, and in the saprophytic ferment the final process was produced, not by one definite organism, but by a series of organisms. He did not think that these ferments destroyed one another; but between the beginning and the end of the putrefaction there was a definite incoming and disappearance of many forms. In from 50° to 60° north latitude, he believed these organisms were limited to ten forms, and of these eight were definitely determined, and their life-history made out. There were some present everywhere, and they acted at once. Dr. Dallinger said the object of his study was biological, and not pathological. Some of the results he discovered some time ago, but the large progress of recent years was due to the great improvements in our instruments. These organisms were all different, no two of them behaved alike. He said that if they added a very small quantity of putrescent fluid to a speck of water on a slide kept at 65° F., it was very easy to find some of these organisms almost directly, using a lens magnifying 1000 diameters; and they would be found to increase with a rapidity that no description could suggest. He then showed on the screen the first kind of organism that appears, and mentioned that when seen in reality, they were in a constant state of movement, and that the saprophytic ferment begins to split up and break down the organic tissues. This first organism, *Bacterium termo*, would produce profound changes in the putrefying tissues, and prepare the way for other organisms. It would be seen that this organism would be densest round the mass that was being broken up, forming a felt-like covering or garment to it; soon a new organism of a spiral form would make its appearance (this was shown on the screen), while *Bacterium termo* would become less abundant, and be diffused over the entire fluid. The new one, like *Bacterium termo*, would be densest next to the putrid matter, and would form a covering to it. The decaying tissue would now rapidly change, and would give off noxious gases. This form would continue for an indefinite time, and be succeeded by one or two new forms. (These were shown on the screen.) One of these new forms would have a single flagellum, and the other would have two; and they would move rapidly about and glide continuously over the decomposing matter. They increased very rapidly, one method of increase being by a process of division. In another method two bodies would unite together, and an amœboid condition ending in the *fusion* of two forms resulting in a sac from whence spore was produced, giving rise to new generations. Their rate of increase was inconceivably rapid, and it was not surprising that the putrid tissue was surrounded by a garment of these organisms. They had in all probability their food and suitable conditions for their life produced by the functions of their predecessors. Then a time came when this form died out, and a very remarkable organism appeared which also invested the putrid matter with a garment of living organisms; they stuck to the mass and waved to and fro. These were shown on the screen as they would be seen in the microscope, clustering round the matter. With this was shown the next organism—a most wonderful one. It has a rigid flagellum armed with a hook and a long trailing flagellum. The animal swims about, and when it comes to a piece of decaying tissue, it often anchors itself by the trailing flagellum, which is coiled into a spiral; then it darts up and down upon the decaying matter. The action of this was shown by a mechanical slide, the up-and-down motion and the coiling and uncoiling of the flagellum being seen. These were succeeded by a group which had a free flagellum without any hook, and which fastens itself down by means of its trailing flagellum, and hammers the decomposing tissue by throwing itself against it. This process was also shown on the screen by means of a mechanical slide. Dr. Dallinger said that this occurred at about the middle of the putrefactive action, the greater part of which is accomplished by this. The mass now gradually broke up. The next kind, which was also shown on the screen, and its process explained by a mechanical slide, has two trailing flagella by which it anchors itself; it then springs up and darts down, and further promotes the decomposition. At the close of this stage there is little left of the original tissue but some water charged with carbonic acid, and a slight deposit of fragments. Dr. Dallinger said that four years ago he found a new organism which acts as a gleaner, and gathers up the fragments of the *débris* left by the others. It is armed with six flagella, and swims about in the liquid, and when it comes within a certain distance of the solid remnants twists its middle flagella together, and springs up and down on the *débris*, removing entirely tiny particles. They move in a most beautifully rhythmic manner up and down. He showed a picture of these on the screen, and also a mechanical slide of a group of three, with their pretty rhythmic action. And thus the organic tissues were broken up into their ultimate elements. Dr. Dallinger mentioned that the last form was comparatively rare, and was more frequent in warm countries. It was clear, he said, that different climates had somewhat different forms. In conclusion, he said that twenty years ago, when in a state of ill-health, he took to this research, and found all these beauties and a thousand times more; and he urged those present to take up some field of microscopical research, and seek for the hidden beauties of Nature. They would find much pleasure in the doing of it. They need not be appalled by the high powers he had used; there were many facts to be found by the help of far lower powers. If they did this they would find that life would have a pleasure it had never known before.

HIGHLAND PLANTS FROM NEW GUINEA.

As we have already noted, Baron von Mueller contributes to the Transactions of the Royal Society of Victoria (vol. i., Part 2) some important records of observations on Sir William MacGregor's highland plants from New Guinea. The following are his general conclusions:—

"The memorable expedition, so valiantly and circumspectly carried out by His Excellency Sir William MacGregor, the Governor of British New Guinea, for the ascent and exploration of the Owen Stanley's Ranges, has for the first time brought also the flora of the temperate and the sub-Alpine zone of that great island within the reach of elucidation. In a brief preliminary report, written in July last, attention was drawn to the extraordinary commigration, by which plants of Asiatic, of far southern and even of sub-Antarctic types had mingled together in the Papuan highlands. From the material thus brought together only a commencement could be made to study the vegetation of the higher mountains regarding geographic points of view; in order to obtain a full insight into the Papuan Alpine flora, it would require to explore the hitherto inaccessible more central culminations in the island, where on tiers still some few or perhaps several thousand feet higher in yonder latitudes, according to varied physical conditions, a glacier flora would be more fully reached. To form extensive conclusions on the nature of the Papuan Alpine flora would at present be premature; but from what we have now seen, it promises to be eminently interesting. On this occasion I shall merely group these highland plants on geographic principles, with a hope that it may yet fall to my own share to carry on these comparisons more amply at some future time from fuller material, the total sub-Alpine and Alpine flora of New Guinea in all likelihood comprising several hundred species of vascular plants. Such future researches will be to myself all the more fascinating, as from 1853 to 1855 the whole flora of the Australian Alps became elucidated by field-work of my own, it being utterly unknown before. In these pages is alluded only to those plants, which Sir William MacGregor gathered in altitudes between 8000 and 13,000 feet, therefore in the region above the mountain zone, involved in almost permanent clouds.

"Of the 80 plants, specifically and distinctly recorded in these

pages as emanating from the most elevated regions, nearly hal the number seems endemic, so far as hitherto can be judged, while not yet all the highlands of South-Eastern Asia are explored, and while we yet remain in uncertainty about the constancy of some of the characteristics on which the adopted new specific forms are systematically established. Of these restricted Papuan plants, two—namely, *Ischnea elachoglossa* and *Decatoca Spencerii* represent new genera, the one allied to the exclusively Italian Nananthea, the other to the Australian and chiefly Alpine Trochocarpa. Of the other endemic plants 17 are of Himalayan types—namely, *Hypericum Macgregorii, Sagina donatioides, Rubus Macgregorii, Anaphalis Mariæ, Myriactis bellidiformis, Vaccinium parvulifolium, V. amblyandrum, V. Helenæ, V. Macbainii, Gaultiera mundula, Rhododendron gracilentum, R. spondylophyllum, R. culminicolum, R. phæochiton, Gentiana Ettingshausenii, Trigonotis Haackei*, and *T. oblita*, though some of these show also a touch of the Sundaic vegetative element; and here at once may be alluded to the extensive display of Ericaceous (inclusive of Vaccinaceous) plants, which forms of vegetation are in Australia so very scantily developed, and then only in Alpine regions. Contrarily, however, we now perceive otherwise almost a preponderance of upland Australian or New Zealandian or sub-Antarctic types in the highlands vegetation of New Guinea, so far as already revealed; this is demonstrated by the endemic occurrence of *Ranunculus amerophyllus, Metrosideros Regelii, Rubus diclinis, Olearia Kernotii, Vittadinia Alinæ, V. macra, Veronica Lendenfeldii, Libocedrus Papuana, Phyllocladus hypophyllus, Schœnus curvulus*, and *Festuca oreoboloides*; furthermore this repetition of the features of the southern flora so far north is rendered still more expressive and significant by the occurrence of numerous plants absolutely identical with our southern species—namely, *Epilobium pedunculare, Galium australe, Lagenophora Billardierii, Styphelia montana, Euphrasia Brownii, Myosotis australis, Sisyrinchium pulchellum, Astelia alpina, Carpha alpina, Carex fissilis, Uncinia riparia, U. Hookerii, Agrostis montana, Danthonia penicillata, Festuca pusilla, Lycopodium scariosum, Gleichenia dicarpa*, and *Dawsonia superba*—most of these being now shown for the first time to approach so near to the equator. Four Borneo plants, hitherto only known from lofty altitudes of Kini-Balu, have now been traced to the Papuan highlands also, viz. *Drimys piperita, Drapetes ericoides, Rhododendron Lowii, Phyllocladus hypophyllus*, three being of far southern type. Even a few of such British plants, not almost universally cosmopolitan, have now come like messengers from home before us from New Guinea as there also indigenous; thus, *Taraxacum officinale* and *Scirpus cæspitosus*, these being wanting even in the Malayan islands and in continental Australia, irrespective of the widely distributed *Aira cæspitosa, Festuca ovina, Lycopodium clavatum, L. Selago*, and perhaps *L. alpinum*, as well as *Hymenophyllum Tunbridgense* and *Aspidium aculeatum*. For the familiar northern genus Potentilla a truly indigenous position in the southern hemisphere has been gained now for phytogeography, as well as for Myriactis and Trigonotis, while Astelia, Uncinia, and Dawsonia are now seen to enter equinoctial regions in the eastern hemisphere. The *Styphelia montana*, the Astelia, and the Carpha mentioned indicate the commencement of a truly Alpine flora.

"On the Finisterre Range, the ascent of which was accomplished by Mr. Zoeller and his party during 1888 (this enterprise being inspired by myself in a lengthened interview with the leader), tree vegetation exists to the summit, therefore up to 11,000 feet, as indeed already telescopically ascertained by M. Mikluho Maclay. I can, however, furnish no data, which might assist our present purpose, on the nature of the vegetation there, as—against my expectation—no botanic specimens whatever, resulting from that courageous exploit, came to me as one who since many years has been engaged occasionally on connected elucidations of the Papuan flora. Sir William MacGregor found the arboreous vegetation to cease on the Owen Stanley's Ranges at 11,500 feet (despatch, July 1889, p. 16), and this cessation was not due to a change of geologic formation. The limits of tree vegetation may, however, on some other Papuan culminations under altered physical conditions be somewhat higher so near to the equator, in comparison to zones of vegetation in the Himalayas at and near the verge of the tropics.

"As regards prospective utilitarian gain from the world of plants likely to emanate from this expedition, we may look forward to the acquisition of the 'cypress' (*Libocedrus Papuana*), which constitutes the principal forests on the summit of Mount Douglas and Winter's Height, for arboreta even of countries of the cool temperate zone, and with this cypress-like tree could doubtless be associated in parks far outside of the tropics also the tall 'bamboo' (see Sir William MacGregor's despatch, p. 8), with which the dry region above the nebular zone begins at (about 8500 feet). The several hardy and gaudy rhododendrons could aptly be consociated by dissemination with the many Sikkin species, now so frequent as garden favourites. The dwarf raspberry would give us an additional table-fruit. How far the Korthalsia palm would bear actual frigour, remains to be ascertained. The species of Papuan highland grasses are rather gregarious than numerous.

"Why so many plants from cold southern latitudes suddenly reappear on the Papuan and perhaps also on the Bornean highlands in evidently coæval forms of common origin; why the highest regions, and these almost only, should, like in New Zealand, reiterate plant-life, otherwise typical of Tasmania, of continental Australia, of islands in the Southern Ocean, and also of Fuegia and Patagonia; whether this indicates a continuity of portions of the Papuan Island with a once vastly extending southern land, now mostly submerged; what clues can be obtained for all this from the study of glacial drifts occurring during former enormous telluric changes, such as geologic science endeavours to explain; what part possibly could have been taken by any migratory birds in effecting so wide a dispersion of some of these plants even into so exceptional isolations; all this and other momentous considerations involved in these questions must be reserved for future discussions and generalizations in a special essay, perhaps under the advantage of access to ampler working material, and at not too distant a day."

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for July contains an article by Prof. H. A. Newton on the late Prof. E. Loomis, of Yale College, U.S. (see NATURE, vol. xl. p. 401). In early life he paid much attention to terrestrial magnetism, and published the first magnetic charts of the United States; but his most important contributions were to meteorology. In a discussion of the storms of 1842, he adopted the use of synchronous charts very much like those now generally employed. The later years of his life were spent in discussing the materials collected by the Signal Service, and he published twenty-three memoirs upon them, entitled "Contributions to Meteorology." A large portion of his estate was bequeathed to the endowment of an astronomical observatory.—Prof. H. A. Hazen has an article setting forth the observations most needed in the study of tornadoes. He points out that, after fifty years' observations, our knowledge of this subject is very unsatisfactory.—Lieut. Finley gives tornado statistics for the States of Florida and South Carolina. The observations for the latter extend over 128 years. The month of greatest frequency in Florida is September, and in South Carolina, March.—M. H. Faye continues his articles on trombes and tornadoes, dealing especially with their action upon forests, and the carrying of heavy *débris* to great distances.—Prof. W. A. Rogers continues his article concerning thermometers, dealing principally with the pulsatory movements of a mercurial column found to exist in nearly all the thermometers investigated.—The last article is devoted to American opinions on the relation of the influenza epidemic to meteorological conditions, being abstracts of papers read at the meeting of the American Medical Association in May last.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, August 6.—Captain H. J. Elwes, Vice-President, in the chair.—Prof. Meldola, F.R.S., exhibited a male specimen of *Polyommatus dorilis*, Hufn., a common European and Asiatic species, which had been taken at Lee, near Ilfracombe, in August 1887, by Mr. Latter. At the time of its capture Mr. Latter supposed the specimen to be a hybrid between *Polyommatus phlæas* and one of the "Blues," and had only recently identified it as belonging

to a well-known species. Mr. Stainton, F.R.S., Mr. Jenner-Weir, and Colonel Swinhoe made some remarks on the specimen, and commented on the additions to the list of butterflies captured in the United Kingdom which had been made of late years.—Mr. W. F. H. Blandford exhibited, and made remarks on, five specimens of *Athous rhombeus*, Ol., recently collected by himself in the New Forest.—The Rev. Dr. Walker exhibited a large collection of Coleoptera which he had recently made in Iceland. The following genera, amongst others, were represented, viz. *Patrobus*, *Nebria*, *Byrrhus*, *Aphodius*, *Philonthus*, *Barynotus*, *Chrysomela*, *Agabus*, *Creophilus*, and *Carabus*. Mr. Champion, Dr. Sharp, F.R.S., and the Chairman made some remarks on the collection.—Captain Elwes exhbited three species of the genus *Atossa*, Moore, three of the genus *Elcysma*, Butl., and three of the genus *Campylotes*, West.,—all from the Himalayas and North-Eastern Asia. The object of the exhibition was to illustrate the remarkable differences of venation in these closely-allied forms of the same family. Colonel Swinhoe, Mr. Warren, and Mr. Moore took part in the discussion which ensued.—Mr. P. Crowley read a paper entitled "Descriptions of Two New Species of Butterflies from the West Coast of Africa," and exhibited the specimens, which he proposed to name respectively *Charaxes gabonica* and *Cymothoe marginata*. He also exhibited several other new species from Sierra Leone, which had been recently described in the *Annals and Mag. of Nat. Hist.*

PARIS.

Academy of Sciences, August 4.—On the exhaustion of land by culture without manure; study of drainage waters, by M. P. P. Dehérain.—Observations of Coggia's comet (July 18, 1890) made with the Brunner equatorial of Toulouse Observatory, by M. E. Cosserat. Observations of position were made on July 21 and 22.—Elements and ephemeris of Denning's comet (July 23, 1890), by M. Charlois. The elements have been calculated from observations made at Nice on July 24, 28, and 30.—*Résumé* of solar observations made at the Royal Observatory of the College of Rome during the second quarter of 1890, by M. P. Tacchini. (See Our Astronomical Column.)—On the density of nitrogen and oxygen according to Regnault, and the composition of air according to Dumas and Boussingault, by M. A. Leduc. The author draws attention to a difference between the results obtained by Regnault and by Dumas and by Boussingault. If x = the proportion of oxygen in 100 volumes of air, d and d' the densities of oxygen and nitrogen, then

$$dx + d(100 - x) = 100, \text{ and } x = \frac{100(1 - d)}{d - d'}.$$

Replacing d and d' by Regnault's values ($d = 1\cdot10563$ and $d' = 0\cdot97137$), we get

$$x = 21\cdot324,$$

and for the percentage composition of air by weight,

$$\text{Oxygen} = 23\cdot58, \text{ and Nitrogen} = 76\cdot42.$$

Dumas's mean value was $23\cdot0 \pm 0\cdot1$, and the author throws out several suggestions as to the probable cause of the discordance. He has also made some determinations of the density of nitrogen, and obtained values comprised between 0·972 and 0·973.—Electrical resistances of gases in a magnetic field, by M. A. Witz. The author has previously communicated his researches on the action of magnetic fields on Geissler tubes (May 12, 1890), and has studied the effects produced by variations in the intensity of the magnetic field and the position of the tube with respect to the lines of force; he has now determined the influence exercised by changes in the pressure of the gas in the tube. The experiments have led to the conclusion that the action of magnets upon Geissler tubes is due to a variation in the capacity of the tubes, so that they constitute true condensers, and their illumination is the result of an oscillatory discharge of the same order as that of a Leyden jar, of which the period T is a function of the capacity C of the jar, and of the coefficient L of self-induction of the conductor of small resistance, and $T = \pi\sqrt{CL}$. A variation of the capacity C would thus modify the vibratory state of the gas and would be the cause of the differences observed in the luminous phenomena in intense magnetic fields.—Reactions of alkaloid salts, by M. Albert Colson. Some investigations on heats of formation are given.—On the division of sulphuretted hydrogen between the metals of two dissolved salts, by M. G. Chesneau.—On some derivatives from acetylacetone, by M. A. Combes.—Experimental researches on thermic sensibility, by M. Charles Henry.—Experimental researches on the affected nerves of chronic lead poisoning, and on the causes determining their appearance, by MM. Combemale and François.—On the combinations of hæmoglobin with carbonic acid, and with a mixture of carbonic acid and oxygen, by M. Christian Bohr.—On the colouring of the silkworm by feeding, by M. Louis Blanc. From the investigations it would appear that very soluble and diffusible substances, such as fuchsin, are absorbed by the epithelium intestinal of the silkworm, and colour the cells of the secretory organs, but not the product of secretion.—On the cellular division of *Spirogyra orthospira*, and on the rearrangement of the colouring matters driven to the ends of the spindle, by M. Degagny.—The treatment of black rot, by M. A. de l'Écluse.

FRESHWATER ALGÆ.

Introduction to Freshwater Algæ, with an Enumeration of all the British Species. By M. C. Cooke, M.A., LL.D., A.L.S. With 13 Plates. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1890.)

DR. COOKE is justified in saying, in his preface, that no apology is needed for the production of this volume, the latest addition to the "International Scientific Series." Notwithstanding the increased attention which has been paid of recent years in this country to this interesting and beautiful class of plants, we have had hitherto no popular hand-book devoted to their structure and their classification; the only existing works on British freshwater Algæ, by Hassall, and by Dr. Cooke himself, having been published at a price which places them out of the reach of the great majority of collectors of Algæ.

More than one-half of the present volume is occupied by a general account of freshwater Algæ, the main points connected with their structure and modes of multiplication, and useful instructions as to their collection and preservation. The greater part of this introductory portion is very good, and will serve admirably to interest and to instruct those who are turning their attention to the collection and determination of the plant-denizens of our streams and pools. In the chapters headed "Polymorphism," "Spontaneous Movements," and "Notable Phenomena," a large mass of interesting information is brought together, and the views of the leading authorities well and clearly presented. In the chapter on "Conjugation," although the present writer naturally dissents from Dr. Cooke's conclusion as to the nature of the process in the Zygnemaceæ, no objection can be taken (except on one minor point) to the way in which both sides of the controversy are presented.

The last two chapters of the Introduction, "The Dual Hypothesis," and "Classification," are much less satisfactory. By the "dual hypothesis" is meant the theory that Lichens are compound organisms made up of a fungal and an algal constituent. Dr. Cooke is, of course, perfectly at liberty to come to a different conclusion on this subject from that of nearly all biologists who have investigated it experimentally; but, at least, if the hypothesis is discussed, the arguments on both sides should be fairly stated. The synthetical construction of a Lichen out of its constituent elements has been affirmed by authorities so worthy of respect as Stahl and Bonnier—a fact which, if established, settles the question in a sense opposite to that accepted by Dr. Cooke; and yet these observations are not even alluded to, much less controverted, by him.[1]

The chapter on Classification is chiefly occupied by animadversions on a system different from that adopted by the author, which has been proposed by other writers on the same subject, "the most pretentious of philosophical systems," which he treats with a certain amount of unphilosophical scorn. Any attempt to classify according to their genetic affinities a class of plants about which so much still remains to be learnt as our freshwater Algæ, must necessarily be to a large extent tentative; but we do not think that practical algologists will be grateful to Dr. Cooke for perpetuating, as the basis of his classification, the obsolete system of Rabenhorst's "Flora Europæa Algarum aquæ dulcis et submarinæ," published in 1864, placing together, for example, *Palmella* and *Apiocystis* in one family, *Protococcus* and *Pediastrum* in another family, and retaining, as a primary group, the "Nematophyceæ." From the sentence on p. 187, the reader would suppose that the separation of the Protophyta as a

structors of paper systems," for whom he expresses so great a contempt, instead of having the sanction of such authorities as Luerssen and Sachs long before these "paper systems" were published.

The latter and smaller part of the work is occupied by a description of the families and genera, and of all the known British species, of freshwater Algæ. Though not so stated on the title-page, the two largest families, the Desmids and Diatoms, are not included; but this was inevitable, to bring the work within moderate compass. The Characeæ, which also form a part of Hassall's "Freshwater Algæ," are likewise, and, as we think, rightly, excluded. The plates include a drawing of one species of each genus; they are copied from the plates in the author's "British Freshwater Algæ," and are not improved in the process. It is no fault of Dr. Cooke's that, with Algæ, even more than with flowering plants, it is often almost impossible to distinguish the species from verbal descriptions only; those given here are mostly taken from the best writers, and could, on the whole, scarcely be improved. Small inexactnesses in spelling or in expression occur with irritating frequency—such as "immovable" for "motionless" in describing the spores of *Chantransia*, "Kutzing" (and Kutz.) throughout for "Kützing," "*Bulbochoete*" for "*Bulbochaete*," "*Glaeocystis*" for "*Gloeocystis*," "cytioderm" for "cytoderm," &c.; but of more serious inaccuracies we have noticed very few. We must, however, enter a word of protest against the Glossary, taken, apparently, almost *verbatim* from the author's "British Freshwater Algæ." A good glossary is an excellent thing; a bad glossary is useless, or worse. What are we to make of such definitions as the following: "ANTHERIDIA, certain reproductive organs supposed (*sic*) to be analogous to anthers, or fecundative"; "CARPOSPORE, spores produced by conjugation (*sic*) in a sporocarpium"? Under the Chroococcaceæ we find a constant reference to a mucous, gelatinous, or crustaceous "thallus"; turning to the glossary, we find a thallus to be "an expansion somewhat resembling a leaf"! "Trichogonia" are "the female reproductive organs in Batrachosperms"; under the Batrachospermeæ we find no reference to any sexual organs of reproduction.

The work, as it stands, will be in the hands of every collector and lover of Algæ. If, in preparing a second edition, Dr. Cooke will consent, in deference to the views of other algologists, to re-write the two chapters in his "Introduction" to which we have called attention,

S

[1] Martelli has quite recently recorded a complementary process in the dissociation of a lichen (*Lecanora subfusca*) into its algal and fungal elements.

and will bring his "Glossary" into harmony with the present condition of science, his "Freshwater Algæ" will have a still higher claim to a permanent place in botanical literature. ALFRED W. BENNETT.

APHASIA, OR LOSS OF SPEECH.

On Aphasia, or Loss of Speech, and the Localization of the Faculty of Articulate Language. By Frederic Bateman, M.D., F.R.C.P., Senior Physician to the Norfolk and Norwich Hospital, &c. Second Edition, greatly enlarged. (London: J. and A. Churchill, 1890.)

THE subject of aphasia has always been, and still is, not only of the greatest interest, but also of the greatest difficulty. Its interest is, of course, largely due to the fact that a study of partial or total loss of language may not only help in an analysis of language itself, but also may throw light on the exact anatomical situation of that function which has been said to set up an insurmountable barrier between man and the lower animals. Its difficulty is greatly increased by the fact that each investigator seems to define it in a different way. For instance, in the book whose title is given above, which is a second and greatly enlarged edition of Dr. Bateman's "Aphasia," first published twenty years ago, two entirely different definitions are accepted as correct. In the opening chapter aphasia is defined as "the term which has recently been given to the loss of faculty of language, and of the power of giving expression to thought, the organs of phonation and of articulation, as well as the intelligence, being unimpaired." On p. 154, however, Dr. Bateman states that he will "employ the term as a title for the whole group of disorders of speech, thus embracing not only the loss, but all the various degrees of impairment, of that faculty." This latter definition will, of course, denote an enormous number of affections, such as all the losses or alterations of speech due to gross cerebral lesions, to insanity, diseases of the medulla, cretinism, deaf-mutism, chorea, and so forth, many of which have hardly been touched upon in this work. The former definition also, in spite of its greater connotation, would include such diseases as deaf-mutism, which is hardly a form of true aphasia.

It is, perhaps, better to limit the term aphasia much more than either of the above definitions would allow. As Ross has so well shown in his small but highly philosophical work, "Aphasia," the mechanisms of speech must include (*a*) the "receptive organs"—that is, the eye, the ear, and the touch (as in reading from raised letters); (*b*) the apperceptive centres in the brain, where the various sensory phenomena are appreciated as language—that is, the angular gyrus and supra-marginal convolutions for written language, and the first temporo-sphenoidal convolution for spoken language; (*c*) the emissive motor centres in the brain at the posterior end of the third left portal convolution (Broca's convolution), from which discharges are sent through the internal capsule to the various organs of phonation; and (*d*) the executive organs, including the nerve nuclei in the medulla, the peripheral nerves from these, and the various muscles of the larynx, pharynx, and tongue. Now of these four sets of organs the first and last should not be included in considering true aphasia so that we should not include as aphasia such disorders of speech as arise from deafness, blindness, bulbar paralysis, or paralysis or other diseases of the larynx or tongue. The two remaining groups, (*b*) and (*c*), alone remain, and the organs of both are situated entirely in the brain, so that we can shortly define aphasia as a disorder of speech due to cerebral disease, the intellect being unaffected. It can, moreover, be seen to be roughly of two kinds—sensory when the apperceptive organs are affected, and motor when the emissive organs are affected. Now on these points Dr. Bateman has not been sufficiently explicit, with the result that some subjects have been included in his work which might well have been left out.

Aphasia may be divided, moreover, as regards causation, into organic where there is a distinct gross lesion, and functional where no known lesion is present. Of the functional causes, hysteria is by far the most common, and is generally the cause of those apparently anomalous cases where speech suddenly vanishes, only to return in as sudden a manner.

Nearly the first hundred pages of the book contain a most excellent account of the history of aphasia from the earliest times; but we regret to notice that while great stress is laid on cases reported more than fifty years ago, when nervous diseases were so little understood and when the examination of aphasic patients was most incomplete, yet the later and most thorough accounts of aphasia are noticed very slightly or not at all. Thus, although we find some slight references to Kussmaul's classical work, and also a slighter account of the works of Ross and Broadbent, Wernicke and Lichtheim are altogether neglected. And be it remembered that these names stand out pre-eminently as writers on this difficult subject.

All through this work there is an undercurrent of disbelief in any possibility of localizing the cerebral situation for speech, and after considering all the various views of localization, from that of Schroeder van der Kolk, who localized it in the corpora olivaria of the medulla oblongata, to that of Broca, with his localization in the posterior part of the third left frontal convolution, the author finally agrees with Kussmaul in saying that "a simple centre of language or seat of speech does not exist in the brain, any more than a seat of the soul exists in a single centre." Indeed, as the author's cases (to which I shall refer immediately) show, he seems to take extraordinary pains to satisfy his readers that Broca's convolution is not the seat of language, as in many cases of aphasia it is entirely unaffected. Nowadays, however, a neurologist does not attempt to fix on Broca's convolution alone as the seat of language, but says that either the supramarginal or angular gyri, or the first temporo-sphenoidal convolution (all on the left side), or their connections with the motor region, are affected, as a rule, in sensory aphasia; or Broca's convolution, or its connections through the internal capsule with the medulla, are affected in motor aphasia. We know now sufficiently well that a lesion at the front of the anterior lobes, or in the motor area proper, would not be accompanied by aphasia, just as we know that a lesion in the other regions mentioned would almost certainly be accompanied by aphasia.

The author's own cases are ten in number, and are of much interest. Cases I. and IV., however, seem to us to have probably been general paralysis of the insane, and therefore not true aphasia, no typical lesion being found in the brain. There is no mention as to whether the pia mater was adherent to the cortex, which would have been probably the case in both instances. Case V. is given as one of disease of the spinal cord producing paraplegia with aphasia, but as no *post-mortem* examination was held, it is impossible to say that there was not a lesion on each side of the brain which would explain the symptoms more simply. In Case VIII., again, no *post-mortem* examination was made, and it appears to us to be a disease of the medulla or pons and not of the brain proper. Cases VI. and X. are evidently both hysterical aphasia, one occurring in a woman at the climacteric period, the other in a man. In the latter case, Dr. Bateman does not consider that it was hysterical, but the whole history of the man appears to us to prove conclusively that it was a typical case of hystero-epilepsy, which is much commoner, even in England, than is supposed. In Cases III. and VII. we have motor aphasia, but without lesion of the anterior lobes, but, inasmuch as the disease was found in the internal capsule, the fibres from Broca's convolution would, of course, be easily affected. Case VII. is again one of motor aphasia, but is rare, as it is accompanied by left hemiplegia instead of the usual right hemiplegia. This, however, is a coincidence which has occasionally been observed, and in which the speech centres seem to be localized on the right side of the brain instead of the left. There appears to have been no *post-mortem* examination in this case. It is much to be regretted that Dr. Bateman has not given better examples from his own experience of the various classes of aphasia, particularly of the sensory variety.

In mentioning the various kinds of aphasia Dr. Bateman describes fifteen different classes. On analyzing these, however, it can be seen that many of these are mere degrees of a larger class, and it would have been much better to have made fewer varieties. Perhaps the most useful division is as follows:—Motor aphasia, including agraphia and aphemia. Sensory aphasia, including word blindness, or inability to understand written language, and word deafness, or inability to understand spoken language. Finally, rather as a result of sensory aphasia, and, as it were, merely a symptom of it, verbal amnesia, in which a patient either constantly uses wrong words, as in paraphasia, or cannot remember the names of things, as in the aphasia of recollection.

Perhaps these cases of verbal aphasia are the most difficult of all to fathom, and they have been the cause of various neurologists assuming that in the brain there is a a definite centre for the understanding and remembrance of nouns, and another for the understanding of propositions. Ross, however, has pointed out that such an assumption is altogether unnecessary, and shows, by a careful analysis of the evolution of language, that in a lesion of any of the various auditory or visual centres such a dissolution of language would occur as would exactly cause inability of understanding propositions or nouns; and, moreover, that highly abstract nouns, such as *virtue*, would disappear first, and, if the injury were greater, then an inability to understand even concrete nouns would occur. In fact, the way in which Ross looks upon all forms of aphasia as mere paralyses, either sensory or motor, is to us the most satisfactory view yet mooted. These highly philosophical explanations have been entirely unnoticed by Dr. Bateman.

A most useful part of this work is a chapter on the medical jurisprudence of aphasia. This is a subject which we believe has not been touched upon in any previous English text-book, and it is of the greatest importance. Undoubtedly in former times many pure aphasics have been considered insane, and so incapacitated for various legal functions. Now, however, the distinction between insanity and aphasia is clear, and although certain cases of aphasia could not be made to understand legal documents, still other cases would have slight difficulty in this respect, and each case would have to be decided on its merits.

The treatment of aphasia is intensely interesting, for, although apparently it is a hopeless task to attempt to form, as it were, new speech centres in the brain, yet it is really wonderful how much may be done in this way by systematic and painstaking efforts.

To summarize briefly, we may say that Dr. Bateman's work is one that should be read by everyone interested in the faculty of language, or in diseases of the nervous system. It contains an enormous amount of valuable material, which has been put together by great labour, and is written by one who has devoted many long years to his subject.

ERNEST S. REYNOLDS.

CHEMICAL CRYSTALLOGRAPHY.

Einleitung in die chemische Krystallographie. Von Dr. A. Fock. (Leipzig: Verlag von Wilhelm Engelmann, 1888.)

IN contradistinction to works on systematic and physical crystallography, this little volume is devoted to crystallography in its far more fascinating relations to chemical constitution. It has been a most noticeable fact that while pure crystallography in its geometrical and physical aspects has been brought to a state of great perfection, our knowledge of the essentially intimate connection between crystallographic form and chemical constitution has until recently been almost at a standstill, and our information upon this branch of the subject is confined to a few isolated facts, many of which even are greatly in need of more complete investigation. As to whether chemists will ever be able to predict with tolerable certainty the crystalline form of a new substance of given composition, opinions among crystallographers are divided, and it may with reason be advanced that, in view of the meagre collection of facts before us, opinions cannot claim to have any real value at all. Since crystallography has commenced to be studied a little more from the side of the chemist, almost every number of the crystallographer's journal, the *Zeitschrift für Krystallographie*, edited by Prof. Groth, contains contributions to our knowledge of such relations. And whether it be ever possible or not to attain the great generalization, if chemists will only more generally tackle the study of crystallography, the subject will at least be raised from its present position of doubt and uncertainty. British chemists

in particular are somewhat behind in this respect, for the dearth of crystallographers in this country, the home of Miller, one of the greatest names in crystallography, is a subject of general remark among Continental workers in this domain of science. What is required is, first, that chemists shall make practical crystallography, the difficulty of becoming skilled in which has been greatly overestimated, one of the essential accessories of their main subject; and secondly, that special care be taken never to permit a series of well-crystallizing bodies, differing chemically from each other in an ascertained manner, to escape being thoroughly investigated crystallographically, with the object of discovering what geometrical differences accompany the constitutional ones.

To those who take up the subject from this standpoint, Dr. Fock's work will be of great assistance in placing before them in a succinct, concise, and very complete manner, the present state of our knowledge. The earlier chapters deal with the history of the growth of the views now entertained as to the nature of the architecture of crystals. Then follow a series of chapters upon the modes of formation of crystals, by resolidification of the fused substance, sublimation and separation from saturated solutions; upon the complicated influence of water of crystallization upon the geometrical form, and the various theories that have been put forward as to the condition of the water in crystals containing it. The nature of double salts, and the evidence of thermochemistry as to the mode of union of the simple salts in the double molecule, are very fully discussed, and form a most interesting chapter. Then follow a series of chapters upon the ultimate structure of crystals, as evidenced by the mode of formation of crystallites, and the order of growth in larger crystals.

By far, however, the most interesting portion of the book is that which deals with the relations between the crystalline form and chemical composition of crystals. The development of the theory of isomorphism is very clearly traced from the first observation of De l'Isle, in 1772, that the sulphates of copper and iron separated in mixed crystals from a solution of the two, to the latest definition of the theory given by Sohncke with reference to his 65 systems of points. The subject of mixed crystals, and the rules which govern their formation, are entered into at length, and their relations to true isomorphism clearly defined. A very suggestive term, that of "physical isomerism," is given to polymorphism, reminding one forcibly of the similarity between the various forms of the same compound or allotropic forms of elementary substances on the one hand, and the isomerism so characteristic of many of the compounds of carbon on the other. The last few chapters of the book are devoted to a *résumé* of all the more important researches upon isogonism or morphotropy—that is, partial or particular-zone isomorphism. The researches of Groth upon the crystallographical relations between the derivatives of benzene naturally take a prominent place in such a description, being, as they were, the first which were instituted in a systematic manner. And here, in spite of many additions which have recently been made in other branches of organic chemistry to our knowledge of such morphotropic relationships, the subject must perforce end for the present, until more facts have been accumulated and observations multiplied. It is not, however, the mere accumulation of records of measurements of isolated compounds which is so much needed, it is the systematic crystallographical investigation of series of compounds whose chemical relationships are indubitably established that will be calculated to throw most light upon the subject. To this end it is earnestly to be desired that British chemists will not merely content themselves, in describing well-crystallizing new compounds, with attaching to them the meaningless terms "prisms" or "tables," but will have their crystallographical characters thoroughly investigated, and their relationships to other compounds of the same or related series definitely made out.

A. E. TUTTON.

OUR BOOK SHELF.

British Rainfall, 1889. By G. J. Symons, F.R.S. (London: Edward Stanford, 1890.)

THIS work deals with the distribution of rain over the British Isles during the year 1889, as observed at nearly 3000 stations in Great Britain and Ireland. The author begins with his usual report for the year, in which he points out rather particularly, the list only dealing with the years 1884–88, that heavy falls of 3, 4 or 5 inches per diem may occur in all parts of the country. Then follows an interesting article on the amount of evaporation, including illustrations of evaporators and numerous tables.

Under the heading "Staff of Observers" the volume contains returns from 299 stations which sent no perfect record in 1888, the losses being 181, resulting in a net gain of 118. The author informs us that this is the largest increase since the year 1882; and we are glad to see that Scotland, which has been retrograding ever since 1883, has at last improved considerably.

Coming now to the rainfall and meteorology of the year 1889, we have, first, notes of some of the principal phenomena, amongst which we may mention the following:—January 6, at Nottingham, an extraordinary thickness (an inch at least) of rime on all the trees, &c.; June 6, at Cambridge Observatory, severest thunderstorm ever remembered.

The observers' notes for the months and for the year contain some interesting information:—In July, at Finchely, Etchingham Park, there were 22 days of absolute drought followed by 15 wet out of the 20 following days; in the same month the traffic for a distance of ten miles was suspended on the upper level of the Caledonian Canal owing to the scarcity of water.

Of the heavy rains in short periods recorded, the highest was that of 3·37 inches per hour, lasting for 12½ minutes, at Petersfield, Compton; but following this, in Warwickshire, 3·64 inches fell in 1 hour 5 minutes—a quantity unequalled at any station in the British Isles for at least ten years. Of the extremes of rainfall for the year, the largest fell at Stye, in Cumberland (152·85 inches), the least at Dingwall, East Ross (14·51 inches).

Among the absolute and partial droughts, of the former the longest was at Cargen in Kirkcudbright, where no rain fell between June 8 and July 9, or for 30 clear days; and of the latter the longest lasted for 45 days from June 3, at Portland, Co. Waterford. The definitions of these two kinds of drought are respectively:—Periods of more than 14 consecutive days absolutely without rain; periods of more than 28 consecutive days, the aggregate rainfall of which does not exceed 0·01 inch per diem.

With regard to the relation of the total rainfall in 1889 to the average, we find that it is 8 per cent. below the true average as well as 13 per cent. below that of 1870–79.

The general tables of the total rainfall for the year are given, with an explanation of their arrangement.

The result of this systematic and laborious task of gathering all these records and observations reflects great credit on the editor, who seems to have spared no pains to insure the accuracy of the information recorded.

Photogravure. By W. T. Wilkinson. (London: Iliffe and Son, 1890.)

THE aim of photographers has long been to produce prints, permanent and artistic in effect, with the delicacy and truthfulness of a photograph from nature. The process of photogravure seems to fulfil these requirements, and for purposes of book illustration should form a most important factor from the commercial point of view. The process is both simple and interesting, and requires little apparatus or material which is not already found even in most amateur's photographic dark rooms.

Mr. Wilkinson describes in this little book a method employed in obtaining a finished plate, the process being divided into six stages. The first is the production of a transparency upon a special (transparency) carbon tissue from the negative; in the second, from the transparency a negative in ordinary carbon tissue is made; the third consists in laying the etching ground upon a polished copper plate; in the fourth the carbon image (second stage) is mounted and developed upon the prepared copper plate; the fifth stage deals with the protection of the margin, and etching and burnishing; and the sixth and last stage gives us the print from the plate, done in much the same manner as copper-plate etchings and mezzotint engravings. The frontispiece, by W. L. Colls, affords a good illustration of a result of this process.

Elements of Euclid. Book I. By Horace Deighton, M.A. New Edition, Revised. (London: George Bell and Sons, 1890.)

THE present edition of Mr. Deighton's book is a great improvement on many of the works on this subject. In addition to the ordinary propositions, the solutions of a large number of important propositions are incorporated in the text with riders attached to them, which will be found useful, since in examinations nowadays more is required than is contained in Euclid.

Abbreviations and other symbols are used throughout, with the exception of the first fifteen propositions, and great clearness is obtained in the propositions and problems by making the construction lines thin, and also by printing the letters referring to the figures in a larger and more conspicuous type.

At the end of Book I. a series of examples is given on the propositions in it, and a short chapter on plane loci is added. This book will be especially instructive to beginners, the author having smoothed the path for those who wish to acquire facility in solving geometrical questions.

Camping Voyages on German Rivers. By Arthur A. Macdonell. (London: Edward Stanford, 1890.)

IN this book Mr. Macdonell gives an account of boating expeditions on German rivers. Some of the streams he describes have already been dealt with in English books, but he may fairly claim that no previous work of the kind is so nearly complete as his own. Every German river—with the exception of the Lahn—which an Englishman would care to see, he has navigated; and his experiences with regard to each are carefully recorded. We need scarcely say that for young and vigorous travellers there is no more delightful way of visiting a beautiful country. It not only provides them with healthy physical exercise, but takes them into the midst of enchanting scenery, and gives them opportunities of becoming intimately acquainted with interesting towns and villages. Mr. Macdonell has thoroughly appreciated the happiness which has thus come in his way; and in this book he contrives to communicate to his readers a good deal of the pleasure with which he recalls his adventures, and depicts what he has seen. The work is based on notes taken down each day in the course of the various voyages, and to some extent this no doubt accounts for the brightness and freshness of the narative. The value of the book is much increased by good maps, of which no fewer than twenty are given.

Epping Forest. By E. N. Buxton. Third Edition. (London: Edward Stanford, 1890.)

WE are glad to welcome a new edition of this excellent little Guide. Mr. Buxton says the idea of writing it occurred to him when he observed how small a percentage of the summer visitors to Epping Forest ever ventured far from the point at which they were set down by train or vehicle. No one to whom this Guide is known will be content to go to Epping Forest without trying to see as much of it as can be conveniently visited. Mr. Buxton has lived all his life in one or other of the Forest parishes, and knows exactly what parts of the subject are most worthy of being fully dealt with. He knows also how to express concisely and clearly all that he wishes to say. For visitors who are interested in natural history he has added some chapters on "the different forms of life which they may expect to find in the course of their rambles."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The "Barking Sands" of the Hawaiian Islands.

ABOUT a year ago NATURE printed my letter from Cairo giving a condensed account of an examination of the Mountain of the Bell (*Jebel Nagous*) on the Gulf of Suez, and of the acoustic phenomenon from which it is named. In continuation of my researches on sonorous sand, which are conducted jointly with Dr. Alexis A. Julien, of New York, I have now visited the so-called "barking sands" on the island of Kauai. These are mentioned in the works of several travellers (Bates, Frink, Bird, Nordhoff, and others), and have a world-wide fame as a natural curiosity; but the printed accounts are rather meagre in details and show their authors to have been unacquainted with similar phenomena elsewhere.

On the south coast of Kauai, in the district of Mana, sand-dunes attaining a height of over one hundred feet extend for a mile or more nearly parallel to the sea, and cover hundreds of acres with the water-worn and wind-blown fragments of shells and coral. The dunes are terminated on the west by bold cliffs (*Pali*) whose base is washed by the sea; at the east end the range terminates in a dune more symmetrical in shape than the majority, having on the land side the appearance of a broadened truncated cone. The sands on the top and on the landward slope of this dune (being about 100 yards from the sea) possess remarkable acoustic properties, likened to the bark of a dog. The dune has a maximum height of 108 feet, but the slope of sonorous sand is only 60 feet above the level field on which it is encroaching. At its steepest part, the angle being quite uniformly 31°, the sand has a notable mobility when perfectly dry, and on disturbing its equilibrium, it rolls in wavelets down the incline, emitting at the same time a deep bass note of a tremulous character. My companion thought the sound resembled the hum of a buzz saw in a planing mill. A vibration is sometimes perceived in the hands or feet of the person moving the sand. The magnitude of the sound is dependent upon the quantity of sand moved, and probably to a certain extent upon the temperature. The drier the sand the greater the amount possessing mobility, and the louder the sound. At the time of my visit the sand was dry to the depth of four or five inches; its temperature three inches beneath the surface was 87° F., that of the air being 83° in the shade (4.30 p.m.).

When a large mass of sand was moved downward I heard the sound at a distance of 105 feet from the base, a light wind

blowing at right angles to the direction. On one occasion horses standing close to the base were disturbed by the rumbling sound. When the sand is clapped between the hands a slight hoot-like sound is heard; but a louder sound is produced by confining it in a bag, dividing the contents into two parts and bringing them together violently. This I had found to be the best way of testing sea-shore sand as to its sonorousness. The sand on the top of the dune is wind-furrowed, and generally coarser than that of the slope of 31°, but this also yielded a sound of unmistakable character when so tested. A bag full of sand will preserve its power for some time, especially if not too frequently manipulated. A creeping vine with a blue or purple blossom (*kolokolo*) thrives on these dunes, and interrupts the sounding slope. I found the main slope 120 feet long at its base; but the places not covered by this vine gave sounds at intervals 160 paces westward. At 94 paces further the sand was non-sonorous.

The native Hawaiians call this place *Nohili*, a word of no specific meaning, and attribute the sound caused by the sand to the spirits of the dead, *uhane*, who grumble at being disturbed; sand-dunes being commonly used for burial-places, especially in early times, as bleached skeletons and well-preserved skulls at several places abundantly show.

Sand of similar properties is reported to occur at *Haula*, about three miles east of Koloa, Kauai; this I did not visit, but, prompted by information communicated by the Hon. Vladimar Knudsen, of Waiawa, I crossed the channel to the little-visited island of Niihau. On the western coast of this islet, at a place called *Kaluakahua*, sonorous sand occurs on the land side of a dune about 100 feet high, and at several points for 600 to 800 feet along the coast. On the chief slope, 36 feet high, the sand has the same mobility, lies at the same angle, and gives when disturbed the same note as the sand of Kauai, but less strong, the slope being so much lower. This locality has been known to the residents of the island for many years, but has never been before announced in print. This range of dunes, driven before the high winds, is advancing southward, and has already covered the road formerly skirting the coast.

The observations made at these places are of especial interest, because they confirm views already advanced by Dr. Julien and myself with regard to the identity of the phenomena on sea-beaches and on hill-sides in arid regions (*Jebel Nagous*, *Rig-i-Kawan*, &c.). The sand of the Hawaiian Islands possesses the acoustic properties of both classes of places; it gives out the same note as that of Jebel Nagous when rolling down the slope, and it yields a peculiar hoot-like sound when struck together in a bag, like the sands of Eigg, of Manchester (Mass.), and other sea-beaches—a property that the sand of Jebel Nagous does not possess. These Hawaiian sands also show how completely independent of material is the acoustic quality, for they are wholly carbonate of lime, whereas sonorous sands of all other localities known to us (now over one hundred in number) are siliceous, being either pure silex or a mixture of the same with silicates, as feldspar.

The theory proposed by Dr. Julien and myself to explain the sonorousness has been editorially noticed in NATURE, but may properly be briefly stated in this connection. We believe the sonorousness in sands of sea-beaches and of deserts to be connected with thin pellicles or films of air, or of gases thence derived, deposited and condensed upon the surface of the sand grains during gradual evaporation after wetting by the seas, lakes, or rains. By virtue of these films the sand grains become separated by elastic cushions of condensed gases, capable of considerable vibration, and whose thickness we have approximately determined. The extent of the vibrations, and the volume and pitch of the sounds thereby produced after any quick disturbance of the sand, we also find to be largely dependent upon the forms, structures, and surfaces of the sand grains, and especially upon their purity, or freedom from fine silt or dust (Proceedings Am. Assoc. Adv. Sci., 38, 1889).

I should be lacking in courtesy if I closed this letter without expressing my great obligations to Mr. H. P. Faye, of Mana, and to Mr. Geo. S. Gay, of Niihau, for both a generous hospitality and a sympathetic assistance in carrying out my investigations. H. CARRINGTON BOLTON.

Honolulu, H.I., May 26.

Relative Growth of Boys and Girls.

A "NOTE" in NATURE of August 14 (p. 376) referring to some measurements made by Herren Geisler and Ulitzsch, on school children at Freiberg (Saxon), speaks of the fact that between the ages of 11 and 16 years girls are taller than boys as if it had not been previously observed and recorded. The fact has been well known for many years, and was first observed by Dr. Bowditch, of Harvard. In a private letter to me dated March 13, 1876, Dr. Bowditch wrote:—"A comparison of the rates of growth of boys and girls shows that in this community girls about 13 years of age are taller and heavier than boys of the same age, and I wish to see how far this is the case in other countries. Quetelet's observations seem to show that it is not the case in Belgium, but some English observations quoted by him indicate that among certain classes of the population in England the same thing is found." Again, on June 10, 1876, he wrote:—"I am exceedingly obliged to you for your letter of April 27, and for the statistics which it contains. It is very interesting to get a confirmation of my observation on the difference between the two sexes about 13 years of age. I shall endeavour to verify your conjecture as to the cause of it. . . . You refer to Quetelet's measurements as being based on only ten observations for each age. Do you understand that the elaborate tables given in his 'Anthropometrie,' p. 417, rest entirely on this small number of observations?" In his paper on "The Growth of Children," published the following year (1877), Prof. Bowditch demonstrated the fact by both tables and diagrams; and in my "Manual of Anthropometry" (1878), and in the Reports of the Anthropometric Committee of the British Association (1880–83), I have given similar evidence of the difference of the sexes in this country. The English tables published by Quetelet mentioned by Dr. Bowditch refer to factory children, and were collected by Stanway, and published in a Report of the Factory Commission so long ago as 1833. Quetelet makes his curves of growth of boys and girls meet at the age of 12 years, but at all other ages the girls are shorter than the boys, but his ten observations (on selected individuals?) at each age were not sufficient to bring out the true difference. The only novelty in the German observations is that the boys do not "catch up" the girls quite so early as they do in England and America. This point, however, can only be decided by a comparison of the actual measurements of the German with those of the English and American children.

Curzon Street, Mayfair, August 16. CHARLES ROBERTS.

The Perseid Meteors.

As I merely expressed a wish that the Perseid shower should be closely watched on the present occasion, in order to ascertain whether the apparent shifting of the radiant was not really due to other causes, I do not think I need enter into any controversy with Mr. Denning on the subject. I will therefore only say that I think his "Catalogue of Radiants," recently published by the Royal Astronomical Society (the most valuable catalogue I think which has yet appeared), seems to me susceptible (as regards the Perseids) of a different interpretation from that which he places on it in his preliminary remarks.

Dublin, August 8. W. H. S. MONCK.

IN reply to Mr. Monck I need only say that I desired no controversy on this subject, but simply to uphold one of the most conclusive facts of my meteoric observations. I arranged my radiants with the utmost care, and on the basis of a practical acquaintance with the facts; and if Mr. Monck considers my results in regard to the Perseids will bear another interpretation, I must be content to wait for the corroboration which future observers will certainly give.

It is singular that so important a feature as the shifting radiant of the Perseids (which I first announced in NATURE, vol. xvi. p. 362) has not yet been adequately investigated. Mr. D. Booth, of Leeds, has, however, effected some observations in recent years (and especially in August 1887), and his results confirm my own. W. F. DENNING.

Bristol.

The Eclipse of Thales.

MR. PAGE, the author of a work entitled "New Light from Old Eclipses," which was noticed in NATURE last April, has forwarded the following communication on the subject of the eclipse of Thales. The views which Mr. Page entertains on the subject of these ancient eclipses are not those generally accepted; but he believes a crucial test of the superiority of his system is afforded by this particular eclipse;

and the author of the notice referred to is therefore invited to furnish a parallel calculation, based upon the theories which have hitherto received general support. This invitation the writer must decline, simply because two far abler hands than his have already investigated this problem on the lines which he would have pursued; and he could add nothing to the authority that accompanies the utterances of Dr. J. R. Hind, the Superintendent of the English "Nautical Almanac," and Prof. Simon Newcomb, the Superintendent of the American.

The following is Mr. Page's communication:—

"Herodotus speaks of the eclipse of Thales as follows:—'A war commenced between the Lydians and the Medes, . . . which continued five years; and it is remarkable that one of their engagements took place in the night. In the sixth year, when they were carrying on the war with nearly equal success, on the occasion of an engagement, it happened that in the heat of battle day was suddenly turned into night' (Herodotus, b. i., s. 74).

"This battle was fought on the morning of the (Julian) July 8, or 9 days after the solstice; consequently in the time of longest days and hottest weather. It would seem from the above account that it commenced in the night, and was not ended until the time of the eclipse, or 5.24 a.m.; when the armies ceased fighting on account of their fears.

"From Ptolemy's canon we learn that Cyaxares, King of Media, began to reign B.C. 634, and reigned 40 years, during 28 of which the Scythians ruled over Asia. In B.C. 606 the Scythian power was broken, and the Medes and Babylonians conquered Assyria. Soon afterwards (*i.e.* in B.C. 603) that war broke out between Lydia and Media which was terminated by mutual fears of this eclipse. As the King of Media reigned 40 years from B.C. 634, he must have died B.C. 594, which is the latest date that can be fixed for the eclipse; and as he was 28 years subject to the Scythians, he must have reigned 12 years after the defeat of the Scythians in B.C. 606; and as his war with the Lydians could not have taken place for several years after this, and as the eclipse was in the sixth year of the war, the date of the eclipse cannot possibly be placed earlier than B.C. 600: consequently we are compelled to look for it some time between B.C. 600 and B.C. 594."

Appended to this communication is a calculation by Mr. Page of the time of new moon in B.C. 597. This calculation is founded upon Ferguson's tables, to which some corrections have been applied by the computer. The calculation cannot be given here in detail; but the result to which Mr. Page is led is July 8, 5h. 24m. 11s., as that at which the so-called eclipse of Thales occurred. This date differs some twelve years from that which has been assigned by the two authorities just mentioned, viz. B.C. 585—a date, too, which accords with that mentioned by Pliny, reckoned by Olympiads. But those who find Mr. Page's arguments sufficient will agree with him; my regret is rather that he has chosen to build his theory on absolute tables, and to ignore all that the ablest astronomers and mathematicians have recently been able to accomplish in this direction. WILLIAM E. PLUMMER.

The Rotation of Mercury.

IN your issue for January 16 (xli. p. 257), Schiaparelli's observations on the planet Mercury are stated to lead that astronomer to the conclusion that "Mercury revolves around the sun in the same manner that the moon revolves round the earth, always presenting to it the same hemisphere."

Permit me to recall the fact that, as a matter of deductive reasoning, I recorded this opinion in 1883: "The powerful tidal action experienced by Mercury has greatly retarded its primitive axial motion, and increased its distance from the sun. No surprise would be occasioned by the proof that the planet has already attained to synchronistic motions" ("World-Life," p. 425). This opinion was accompanied by calculations of the solar tidal efficiency on Mercury.

ALEXANDER WINCHELL.

Wet and Dry Bulb Thermometers.

IT may, perhaps, interest you to know that on Friday last the difference between the wet and dry bulb thermometers, on board this ship in Grimsby roads, amounted to 12½°; the dry bulb showing 66°, and the wet bulb 53°·5. Wind west; force, 7 to 8 by Beaufort's scale. This is the greatest difference I have recorded in this country for ten years. T. H. TIZARD.

H.M.S. *Triton*, Grimsby, August 17.

Experiment in Subjective Colours.

THE following experiment does not seem to be widely known: it is not easy to make a clear explanation of the lenses.

Take a number of the *Graphic* and a piece of thin paper, which, if put upon the ordinary print, allows it to be seen through, as black. Now put the paper over some of the large black letters on the apple-green outer cover: seen through the paper, they appear as bright red. W. B. CROFT.

Winchester College, August 18.

THE SCIENCE AND ART MUSEUM, DUBLIN, AND THE NATIONAL LIBRARY OF IRELAND.

IN the year 1877 the Natural History Museum and the Library of the Royal Dublin Society, which, though mainly supported for many years by Parliamentary grants, had been directly managed by the Society, were, by Act of Parliament, transferred to the Science and Art Department, a large sum of money having been at the same time paid by Government to the Society for ceding its rights and property.

Soon afterwards steps were taken by the Science and Art Department for providing suitable accommodation for an art and industrial addition to the Museum. Into a consideration of the various causes which delayed the carrying out of this project we need not enter here; they will be found described in the Reports of the Science and Art Department.

At length, in 1884, a final competition between rival architects' designs for the new buildings was arrived at, and those by Messrs. Deane and Son, of Dublin, were chosen by the representative committee, which was specially appointed for the purpose of selection.

The sites for these buildings, which were adopted after much discussion, are at right angles to Leinster House on its Kildare Street or western side. The *façades* of both buildings, which face one another, are about 200 feet long, and are similar, consisting of two rotundas with colonnades, and pavilions at the sides. In the centre of the Museum building is a large court about 125 feet by 75 feet. Opening from it there are in all 24 galleries or rooms, which are devoted to exhibiting purposes.

The foundations were laid by His Royal Highness the Prince of Wales on April 10, 1885, the ceremony connected therewith being the most important presided over by His Royal Highness during his last visit to Ireland.

The tender for the erection of the buildings by Messrs. Beckett Brothers, of Dublin, was accepted on November 3, and by the 17th operations had commenced. In four years, or by November 1889, the Museum building was completed, and was handed over to the Science and Art Department, and the transfer to the new galleries of the collections which had accumulated in the temporary premises during twelve years was at once proceeded with.

It was not until June of the present year that the sister building, for the reception of the National Library of Ireland, was completed. During the month of July the transfer of the books, consisting of about 100,000 volumes, from the old Library in Leinster House, has been satisfactorily accomplished.

Both institutions are about to be opened on the 29th of the present month by His Excellency the Lord-Lieutenant, after which they will continue to remain open, and free to the public.

It may be of interest to add some details as to the principal contents and system of arrangement in the two institutions respectively. In order to describe the Museum

effectively, it is necessary to include here an account of the collections in the Natural History Department, which, however, remain in their old quarters—a very suitable building on Leinster Lawn. It has for a pendant a similar building, the National Gallery of Painting, which is, however, under different management. The relative positions of the five buildings may be compared to a capital H, in which the cross bar represents Leinster House, and the other portions of the letter the four buildings which have been referred to, with Leinster Lawn and the courtyard of Leinster House between them. Close by there is another group of buildings, which contains the class-rooms of the Metropolitan School of Art.

Leinster House, which is comparable in a sense to Burlington House, affords accommodation to the officers of the Science and Art Department in administrative charge of the various institutions, and also to the Royal Dublin Society, which, since it has been relieved of its mangement of the several institutions, has considerably developed its various functions in science and agriculture; for the due carrying out of the latter it has provided itself with extensive show yards at Ball's Bridge in the suburbs of Dublin, where the cattle shows, &c., have acquired an importance and success never attained while they continued to be held in the City premises.

The Society is possessed, moreover, of a large private library, and its members enjoy various privileges, such as the use of a general reading-room, free admission to meetings, lectures, &c. The Society has recently entered upon several new lines for the development and encouragement of the arts and industries of Ireland.

Returning to the Museum—the building which contains the natural history collection consists of two large rooms or halls, one on the basement and the other on the first floor, the latter having two galleries. The basement room contains the systematic collections of fish, reptiles, a number of large recent and fossil skeletons, and groups illustrative of the geographical distribution of animals.

In the lobby of the first-floor room there is a special collection of the mammals of Great Britain and Ireland, and in the room itself the main systematic collection of mammals is arranged in a row of large central cases, and the invertebrate collections in table and wall cases at the sides. As in some of the other groups, there are special collections of Irish invertebrates.

The first gallery contains a general collection of stuffed birds, and a special collection of Irish birds. In the second gallery there are general collections of insects, and of birds' nests and eggs. A room off this gallery contains a large collection of birds' skins arranged in glazed drawers, for study. Besides the above, there are considerable collections of invertebrates—especially of insects—in the curators' rooms.

A large annex, which was formerly occupied temporarily by a portion of the art collections, has been made use of for the display of the palæontological collections, which are of some extent and importance. The specimens of plant and animal fossils are for the most part arranged systematically; they include large numbers of fossils from the Sivalik Hills in India, and many well-known casts of generalized types of animals. The special collections, not incorporated, include an extensive one of Irish mammals, Sir Richard Griffith's collection of Irish Carboniferous and Silurian fossils, and several collections of Arctic fossils made by Sir F. Leopold McClintock and others.

From this annex a passage affords access to the new building which is about to be opened. In the first two rooms the collections of fossils, rocks, and minerals, which have been made by the Geological Survey of Ireland, are exhibited. In an adjoining room there is the general Museum collection of minerals, with a small one of meteorites. The next room is devoted to a large relief map of Ireland, coloured geologically. It is on the horizontal scale of one inch to a mile, the vertical scale, as is usual, being considerably exaggerated. In this room there are also a number of photographs representing natural phenomena, including some large transparencies which were presented by the United States Government. The corresponding rooms on the other side of the building are devoted respectively to (1) Greece and Rome; (2) Egypt and Assyria; (3) Ethnography, a very extensive and important collection; (4) Musical instruments; (5) India and Persia.

The Central Court, from which these rooms open off, is devoted mainly to casts of antique and mediæval sculptures, and to a large number of models of statues and busts by the late J. H. Foley. Close by is the rotunda, a hall which has been compared to Napoleon's tomb. It contains casts of antique sculptures, and in the centre a group of three bronze guns, with their carriages, &c., which were taken at Sobraon and Maharajpur, and presented to Lord Gough by the Honourable East India Company.

Ascending to the first floor, we meet in succession rooms devoted to (1) textiles (lace and embroidery); (2) wood carving; (3) glass and ceramics; (4) furniture; (5) casts of ivories and metal-work; and on the opposite side (1) woven materials, models of looms, &c.; (2) industrial models; (3) and (4) rooms intended for the famous collections of Irish antiquities made by the Royal Irish Academy; and (5) arms and armour. The gallery of the Central Court contains a number of casts of Celtic antiquities, a large collection of metal-work, and electrotypes, besides many other objects of considerable interest. In the gallery of the rotunda there are a number of casts of modern sculptures, &c.

On the south side of the building there is a second floor containing four rooms; these have been allotted to the Herbarium and Botanical Museum, the collections included in which are considerable, having been brought together from many different quarters. They have not yet, however, been arranged for public inspection. The various collections of Cryptogams are, perhaps, the most valuable. There are also several well-known collections of Irish plants.

It will be seen from the above sketch that this Museum covers a very wide field. This will be still further apparent from a study of the general "Guide" which is about to be issued.

There are some special features in the arrangement of the specimens which may be touched upon briefly. The objects in the Museum are largely provided with fully descriptive labels and maps. In the mounting of the specimens many novel devices have been made use of, and some ingenious contrivances have been founded upon inventions which, though used in American museums, have not hitherto been adopted in Europe.

The Museum is open free to the public daily, Sunday and two week-day evenings being included. The daily average attendance is about 600, and there is every reason for believing that the institution, which is now about to be fairly launched on its more extended career, will become increasingly popular and increasingly instructive to the people of Ireland.

The National Library is being arranged in its new quarters, upon principles which have been for many years the subject of earnest consideration and study by the librarian, Mr. William Archer, F.R.S.

The principal public reading-room is a very handsome apartment, capable of accommodating 200 readers. With the exception of a few works of reference, such as dictionaries, &c., the books are all arranged in stores, which are close at hand, in one of the wings of the building. These stores are in five stories, which are connected by ordinary (not spiral) stairs of low gradient, and the books are arranged on free standing presses, within easy reach of hand and eye; thus no ladders are

required, and no wall presses are used. Although the ultimate potential storage capacity of the building when complete may be extended to 600,000 volumes, at present only about 100,000 have to be provided for.

The arrangement of the books is according to a modification of the decimal system of Mr. Dewey, of the State Library of New York. It is claimed for this system that it brings together on the shelves all works of cognate character, be they general or specific.

Within the space available here it is not possible to fully illustrate this system, but a few lines may be devoted to explaining the general principles of the method. The whole Library must be regarded as being divided into nine libraries, numbered as follows: (1) Philosophy, (2) Religion, &c., (5) Natural Science, and up to (9) History. Each of these is again divisible, *if necessary*, into nine parts.

Thus the number 54 represents the 4th division (Chemistry) of the 5th class (Natural Science); 541 represents Theoretical Chemistry, and 5412 represents the 2nd division (Atomic Theory) of Theoretical Chemistry.

Every book as it is received in the Library will receive a number, which will at the same time indicate its place on the shelves, and be a summary of its contents.

When he receives the *title* from a reader, the attendant will, after a little practice, be able to go directly and without reference to the place marks, to the exact shelf or quarter of the stores by simply translating the title into its corresponding number.

One advantage of the system is that the special works contained in the Library on a given subject can always be seen together at a glance. It is needless to point out that the complex character of many books will furnish complex exceptions to the more simple nomenclature.

The Library, as an all-round, modern, working student's library in science and literature, is a very valuable one, though it is not at present so in the sense that it contains any particular literary treasures.

The administration of these several institutions, together with the Botanic Gardens at Glasnevin, and the Metropolitan School of Art, is carried on by the Science and Art Department, which is represented locally by the Director of the Science and Art Museum, under whom there are heads of the several departments and institutions. Two local bodies were created in 1877 to aid the Department in the supervision of these institutions, one the Board of Visitors of the Museum and Botanic Gardens, and the other the Council of Trustees of the National Library, the functions of the latter including the selection of books for the Library.

The total cost of the several institutions is provided in the annual estimates of the Science and Art Department which are voted by Parliament.

COMPARISON OF THE SPECTRA OF NEBULÆ AND STARS OF GROUPS I. AND II. WITH THOSE OF COMETS AND AURORÆ.[1]

II.

General Comparisons.

IN the preceding article I showed that the spectra of nebulæ, auroræ, bright-line stars, and stars of Group II. are closely related to the spectra of comets. In the table which follows, all the spectra are brought together and compared. It is not sufficient to show that each group resembles comets in some respects, as each one might have some feature which was absent in the other. I therefore give the following table to show how far they resemble each other. In the last column the dark bands which are simply due to absence of radiation, and are not really absorption-bands, are omitted.

Nebulæ.	Aurora.	Comets.	Bright-line Stars.	Stars with Mixed Flutings.
4101	411	—	4101	—
—	426	[426]	—	—
—	431	431	—	449 (bright space)
434	435	—	434	—
447	—	—	—	—
—	—	—	—	461–451 bright
468–474	474–478	468–474	468–474	472–476 bright
479	482	483	—	—
486	486	486	486	—
4958	—	—	—	4958–486 bright
500	500	500	—	502–4959 dark
509	—	—	507	—
517	517	517	517	516–502 bright
—	519	519	—	—

—	535	—	—	—
—	539	—	540	—
546	545	546	—	544–551 dark
554	—	—	—	—
559	558	558	558	559–564 dark
—	—	561	—	—
—	—	564	564	—
—	—	568	568	—
—	—	[579]	579	—
—	—	—	—	585–594 dark
5872 (D_3)	—	—	5872	—
—	—	[589]	589	—
—	606	—	—	—
—	620	[615]	—	616–630 dark
—	630	—	635	—

It will be seen that there are three flutings which run through the five columns, namely, 468–474, 517, and 558—these are due to carbon and manganese, and are the familiar cometary bands; four more—hydrogen 486, magnesium 500, magnesium 521, and lead 546—occur in four out of the five columns. Out of the thirty-four lines or flutings given, there are nineteen which occur in less than three columns, but this number is greatly reduced when slight differences of temperature, masking effects, and the exceptional conditions of comets are taken into account.

It is now universally agreed that comets are swarms of meteorites, and the tables which I have given show that nebulæ, bright-line stars, stars with mixed flutings, and the aurora, have spectra closely resembling those of comets, the special features of which are the carbon bands, to which I have recently added the absorption bands of manganese and lead; all are therefore probably meteoritic phenomena.

The following is a list of the bodies which contain either one or both of the carbon flutings near 517 and 468–474, the latter being a group of flutings, which, as I have before shown (Roy. Soc. Proc., vol. 35, p. 167), sometimes has its point of maximum brightness shifted from 474 to 468. The fluting near 564 has been omitted from the table, as it is generally masked, either by continuous spectrum or by the superposition of the fluting of manganese near 558. The wave-lengths given are as measured by the various observers stated.

The spectrum of the aurora is added for the sake of completeness.

It will be seen from the table that the record of the presence of carbon is unbroken from a planetary nebula through stars with bright lines to those resembling α Herculis, *i.e.* entirely through Groups I. and II. of my classification.

We have now to inquire into the previous work on this subject.

Carbon in Stellar Spectra.

Secchi, in 1869, was the first to call attention to the possible existence of indications of carbon in stellar spectra in connection with stars of his types III. and IV.[1] He even compared the spectrum of 152 Schjellerup with the carbon spectrum obtained from benzene. His micrometric measures of the distances of the principal bands in the two spectra from the sodium line D gave great weight to his statement.[2]

But although Secchi observed the coincidence of the edges of two dark bands in his types III. and IV., and remarked that the light-curve in one case faded towards the red, and in the other towards the violet end of the spectrum, he did not recognize that we were dealing with radiation in one case and absorption in the other.

Indeed, Secchi regarded type IV. as presenting chiefly radiation phenomena, for later,[3] when writing with respect to stars of this type he states :—

"Quelques-unes des raies noires et les plus importantes, coïncident à très-peu-près avec celles du troisième type ; cependant le spectre, dans son ensemble, *se présente comme un spectre direct appartenant à un corps gazeux*, plutôt que comme un spectre d'absorption. Si on le considère comme un spectre d'absorption, on trouve qu'il présente le caractère des composés du charbon, tels qu'on les obtient en produisant une série d'étincelles électriques dans un mélange de vapeur de benzine et d'air atmosphérique et dans l'arc voltaique entres les charbons."

From the foregoing, it is evident that Secchi had observed the coincidence of the flutings of carbon with the dark flutings in stars in his fourth type, but missed the significance of it altogether.

[1] *Atti dell' Acad. de' Nuovi Lincei*, xxv., 1872.

[2] These and other comparisons led Secchi to note :—"La conclusione è che nelle stelle di 4° tipo vi é certo il carbonio in una combinazione di debole tensione coll' idrogeno, é che questa combinazione esiste nello stesso stato, o in altro prossimo anche in quello di 3° tipo."

[3] "Le Soleil," vol. ii. p. 458.

Dr. Huggins, however, in a footnote to the first edition of Schellen's "Spectrum Analysis," edited by him, gave an observation of his of the spectrum of 152 Schj., and a diagram of the spectrum of this star, which combated Secchi's work. In his words :—

"He compared the spectrum of the star, using a narrow slit, with the bright lines of sodium and carbon. The line marked D he found to be coincident with that of sodium. The less refrangible boundary of the first of the three principal bright bands in the spectrum of carbon is nearly coincident with the beginning of the first group of dark lines ; the second of the carbon bands is less refrangible than the second group in the star ; the third band of the carbon spectrum falls on the bright space between the second and third group of dark lines in the spectrum of the star. The absorption bands are therefore not due to carbon."

Vogel, in 1884, showed that Dr. Huggins's observations were inaccurate ; that the bands really did coincide with the carbon bands ; and that Secchi's statement was perfectly correct with regard to this star (152 Schjellerup).[1]

[1] "Neben dem Spectrum des Natriums erschienen noch ganz schwach zwei Banden des Alkohol-spectrums, die vollkommen mit den dunklen Banden des Sternspectrums zu coincidiren schienen. Der Anfang der ersten Bande des Alkoholspectrums wurde zu + 14′ 37″ gemessen. Auf den Anfang der zweiten Bande wurde wiederholt der Faden gestellt, und coincidirte jedesmal der Faden so vollkommen als möglich mit der Bande im Sternspectrum. Auch directe Vergleichungen zwischen Alkoholspectrum und Sternspectrum konnten gemacht werden, da das Sternspectrum hell genug war und sich ganz gut von den das ganze Gesichtsfeld durchsetzenden mattleuchtenden Banden des Alkoholspectrums abhob." Following some measures made on June 1, it is noted :—"Bei den Vergleichungen mit dem Natrium- und Alkoholspectrum wurde wiederholt die Ueberzeugung gewonnen, dass eine Coincidens mit den Natrium-Linien, sowie mit den beiden stärksten Banden des Kohlenwasserstoffspectrums im Spectrum der Flammen und des Sternes stattfand. Ich setzte an diesem Abend, da der Himmel besonders gunstig war, noch das stark zerstreuende Rutherfurd'sche Prisma ein und konnte damit wenigstens die beiden stärksten Banden im Sternspectrum messen und wiederum durch directe Vergleichung die absolute Coincidenz der hellsten Bande des Kohlenwasserstoffspectrums mit einer Bande des Sternspectrums beobachten." In summing up the observations of the spectrum of this star Prof. Vogel remarked, "Vergleicht man diese Beobachtungen mit den Seite 14 angeführten des Kohlenwasserstoffes, so ergiebt sich zweifellos das Vorhandensein von Kohlenwasserstoff in der Atmosphäre des Sternes."—"Astrophysikalischen Observatoriums zu Potsdam," No. 14, p. 23, 1884.

Similar comparisons of the carbon spectrum with the spectra of other stars of the same type were made, and the coincidences led Vogel to the following final conclusion:

"Die charakteristischen Banden dieser Sternspectra scheinen durch die Absorption von Kohlenwasserstoffen, die in der Atmosphäre der betreffenden Sterne vorhanden sind, hervorgebracht zu werden."

Quite recently, Mr. Maunder, in commenting upon the Rev. T. E. Espin's admirable revision of Birmingham's "Red Star Catalogue," wrote:[1] "In the note on No. 364 [152 Schjellerup], it should surely have been made clear that the difference between Secchi's and Huggins's account of its spectrum was due to the one having compared it with the spectrum of a hydrocarbon, and the other with that of carbonic oxide, and that the perfect accuracy of Huggins's description has been abundantly confirmed, though, for the reason just given, he missed the recognition of the absorption bands of the stellar spectrum as those of carbon."

Mr. Maunder here refers—I presume with authority—to a statement made by Dr. Huggins which I have not been able to trace. In the note already quoted, Dr. Huggins refers to the spectrum of carbon without giving any idea of the actual compound used for making the comparison, and I have not been able to find any subsequent statement which justifies Mr. Maunder's remarks. Further, it is not sufficient to simply state the compound used, as the spectrum obtained depends upon the conditions of experiment. It does not follow, therefore, that, even if carbonic oxide were employed, the spectrum obtained was not the so-called "hydrocarbon" spectrum. I fancy that now most workers are agreed that the band at 517 is a true carbon band, and obtainable, therefore, from any carbon compound.

Dunér, in 1884, discussed the evidence as to carbon absorption in stars of type IV.[2] The mean wave-lengths given by him for the bands in this group are compared with those found by Vogel in the following table:—

Number of Dunér's band.	Wave-length.	Vogel's measures.	
	$\mu\mu$		$\mu\mu$
		Spectrum begins	660
		Band	656
2	621	... Band	622
3	604·8	... Band	606·5
4	589·8	... Line in a band	589·3
		End of the band	584·8
5	576·0	... Line	575·7
6 (beginning)..	563·3	... Line, beginning of a band	563·1
7	551	... Line	552
6 (end)	545	... Line	544
8	528·3	... Group of lines	528
9 (beginning)..	516·3	... Line, beginning of a band	515·9
		Line	513·2
9 (end)	496		
10 (beginning)..	472·7	... Beginning of a band ...	472·9
10 (end)	463		
End of spectrum	437	... Band	437
		Spectrum ends	430

Dunér compared Vogel's measures and his own with the following wave-lengths of the hydrocarbon bands said to be given by Hasselberg:—[3]

[1] *Observatory*, No. 164, July 1890.
[2] "Sur les Étoiles à Spectres de la Troisième Classe," Stockholm, 1884.
[3] "Ueber die Spectra der Cometen," p. 21.

These values differ slightly from those measured by Hasselberg in 1880, and given in the work referred to by Dunér.

From a comparison of the two sets of wave-lengths, those found in the spectrum of a body of type IV. and those given by Hasselberg, Dunér concluded that:—

"Les longueurs d'onde des bandes 6, 9 et 10 dans les spectres III.*b* sont donc à considérer comme identiques à celles des bandes 2, 3, et 4 dans le spectre de l'hydrogène carboné. Mais aussi la longueur d'onde 437 de la bande au violet, où pour mon réfracteur était la fin du spectre, et la longueur d'onde 430 de la fin du spectre visible, selon M. Vogel, sont d'accord avec les deux bandes violettes de l'hydrogène carboné. On peut donc régarder comme extrèmement probable que:

"*Les bandes principales dans les spectres III.b sont dues à l'absorption exercée par un composé du carbon qui se trouve dans les atmosphères de ces étoiles.*"[1]

It will be seen from the passage which I have given in a note that most of the discussion had turned on the coincidence between bright carbon bands seen in the laboratory and dark absorption bands seen in stellar spectra (type IV.). It is not a little curious to see Dunér, in the passage I have underlined, holding to a possible similarity between stellar and cometary structure based upon carbon radiating in one case and absorbing in the other.

The next important advance was made by Dr. Copeland, who, in January 1886, in a communication to the Royal Astronomical Society on the spectrum of a new star in Orion, wrote as follows:—[2]

"The spectrum is unmistakably of the third type, of which α Orionis is the brightest member. But in this star the *bright bands* are so strikingly developed that they form the most salient parts of the spectrum. Adopting this view an examination of the preceding numbers and the descriptions of the bands, &c., to which they refer, reveals the startling fact that this spectrum is not so much a continuous one, interrupted by dark lines and dusky bands, as a *not very luminous spectrum upon which a series of bright bands are superposed.* One of the bright bands, that beginning with the 'very bright line,' W.L. 516·2 m.m.m. is most readily identifiable as

[1] Dunér, in his conclusions as to the spectra of stars of Class III., wrote:—

"Si l'on passe ensuite à considérer le développement ultérieur de l'étoile, il est évident qu'à mesure qu'elle se refroidit davantage, elle parvient enfin à une température ou le carbone qui doit se trouver en abondance, soit dans son atmosphère soit sous une forme quelconque dans son photosphère, peut se combiner avec l'élément l'hydrogène ou un autre, qui ensemble avec le carbone donne origine au 'Spectre de Swan.' A partir de cela, le spectre se montre coupé par une large et faible bande à la longueur d'onde 516 mm., et par une autre encore plus pâle à 473 mm., et les parties du spectre au-delà de celle-ci sont très faibles. Mais peu à peu ces deux bandes gagnent en intensité, et en même temps la bande à 563 mm. se fait valoir, d'abord à peine visible, puis de plus en plus forte. A cette époque se développe la bande étroite à 576 mm., et finalement les trois bandes principales sont presque égales entre elles en intensité, et on reconnait, dans le spectre, tous les détails caractéristiques. Ce serait s'engager dans une discussion inutile si l'on voulait seulement exprimer une supposition sur le moment ou les bandes secondaires dans le rouge et dans l'orange font leur apparition, aucun fait n'étant connu qui pût être cité à l'appui.

"Ce qui est sans doute très remarquable c'est que dans les spectres III.*b* on n'aperçoit trace de la bande carbonique à la longueur d'onde 618·7 mm. laquelle est si brillante dans les tubes de Plücker contenant de l'hydrogène carboné. Ceci est au reste en parfaite analogie avec ce qu'on voit dans les spectres des comètes qui doivent leur apparence au même composé carbonique qui les spectres stellaires III.*b*, et il y a des analogies aussi pour les autres bandes. Ainsi la bande à 563 mm. est souvent bien faible même dans de brillan[illegible] da[illegible] ass[illegible] seulement un peu plus faible que la bande dans le vert; mais il faut souvenir qu'elle est située dans une partie déjà très faible dans les spectres des étoiles. Il est donc fort possible qu'un affaiblissement médiocre suffise pour rendre entièrement imperceptible la lumière restante. *Il n'y a donc peut-être pas à voir dans cela une diversité entre les comètes et ces étoiles.* Quant aux bandes violettes, elles sont très faibles dans les tubes de Plücker mais fortes dans le spectre de la flamme de l'alcool. On en a vu une trace dans les spectres des comètes les plus brillantes. Dans les étoiles III.*b* très brillantes et pas trop rouges, on a aussi une zone violette laquelle se termine, comme les mesures montrent, à la longueur d'onde 430 mm. donc à la position de la seconde de ces bandes, et à la position de la première il y a, dans les spectres de ces étoiles, une bande."

[2] *Monthly Notices R.A.S.*, vol. xlvi., p. 112

the great hydro-carbon band seen in the spectrum of every comet that has been examined under favourable circumstances. This identification is strongly supported by the second bright line, 513·7, which is also found both in hydro-carbon and cometary spectra. It is, however, on bringing the spectra of the star and of the blue flame of a spirit-lamp at the same time into the field of the spectroscope that their exact agreement becomes most evident. For not only do they agree perfectly in wave-length and in beginning with two plainly distinguishable bright lines, but also in the delicate gradations of light by which they similarly fade away towards the violet, thus forcing the extreme probability of a common origin upon the observer.

"But the presence of luminous lines does not rest on this single band, for the second cometary and hydro-carbon band which has its bright edge at W.L. 472·9 (Hasselberg, 'Ueber die Spectra der Cometen') is also found in the new star's spectrum at W.L. 472·2.

"Of the three other luminous bands agreeing with the coal-gas spectrum, which were all measured at Dun Echt in that of comet 1881 III.,[1] two lie beyond the limit to which I have yet traced the spectrum of this star, and the third, falling between W.L. 563 and 534, in a bright and otherwise difficult part of the spectrum, has not made its possible presence evident.

"This leaves the origin of the bright bands beginning at 542·8 and 494·4 an open question; but excepting their general appearance, there is no reason why they should be due to the same substance as the great band at 516·2. On the other hand, the presence of the bright hydro-carbon bands in a spectrum of type III. removes any difficulty there may be in accepting Secchi's conclusion that they appear in a reversed (dark) form in spectra of type IV."

Dr. Copeland also made determinations of the position of the bright bands in Nova Andromedæ,[2] and noted—

"It seems probable that the three 'bright' bands, of wave-lengths 546·8, 514·0, and 489·2, are identical with the three brightest bands afterwards measured with the same apparatus in Mr. Gore's Nova Orionis, of which the brightest parts were at wave-lengths 542·8, 516·2, and 494·4. The trace of a condensation of light at W.L. 471·6, seen on September 20, agrees well with the bright line in Nova Orionis at W.L. 472·2. . . . In conclusion, it seems worthy of remark that the spectrum described above is the same as that given by any ordinary hydro-carbon flame, burning so feebly that the spectrum of the blue base of the flame is just beginning to show through the continuous spectrum afforded by the white part of the flame."

Vogel made some observations of Nova Orionis,[3] and found that the wave-lengths of the absorption bands were the same as those of α Orionis and other stars of that group, the only difference being that the bright spaces were more strongly marked. Dunér also noted[4] very bright parts in the green and blue, which he identified as the bright zones 516·8–503·2 and 495·8–484·3. With respect to these bright parts, he thought they may be partly due to the contrast with the very dark and broad bands.

M. Ch. Trépied observed that the spectrum of Nova Orionis was like α Orionis and β Pegasi. He also remarked:—[5]

"Le 23 décembre, j'ai, pour la première fois, soupçonné l'existence de lignes brillantes dans le vert; mais cette observation est un peu incertaine. On sait combien il est difficile de décider si les apparences de lignes ou de bandes brillantes, dans un spectre faible, sont vraiment celles qui caractérisent l'état d'incandescence d'une matière gazeuse, ou s'il faut les attribuer à un effet de contraste causé par le voisinage des bandes obscures."

[1] *Copernicus*, vol. ii. p. 227.
[2] *Monthly Notices*, vol. xlvii. p. 54.
[3] *Astr. Nachr.*, No. 2704.
[4] *Astr. Nachr.*, No. 2707.
[5] *Comptes rendus*, vol. cii. p. 41, 1886.

M. Thollon observed the same Nova, and recorded—[1]

"Ce qui nous frappa tout d'abord fut l'éclat remarquable du rouge et surtout du vert, tandis que le jaune était relativement sombre. Cette particularité nous suggéra d'abord l'idée que nous nous trouvions en présence d'un spectre de bands brillantes, analogue à celui des comètes, mais bien plus compliqué. Les observations comparatives faites sur α d'Orion nous confirmèrent dans cette idée. Cette étoile, en effet, montre avec une parfaite évidence un spectre continu conservant partout l'éclat qui lui est propre, et coupé par des bandes et raies obscures."

With the exception of Dr. Copeland, however, no observer confronted the spectrum of the Nova with that of carbon, or the identification of the bright spaces with the carbon flutings would have been evident.

A short time after Dr. Copeland had published his observations, Mr. Maunder challenged the assertion[2] that in the Nova "the spectrum is not so much a continuous one, interrupted by dark lines and dusky bands, as *a not very luminous spectrum upon which a series of bright bands are superposed.*" The accuracy of the observations was not, however, doubted, nor was the importance of the view denied.

The main objection urged by Mr. Maunder was that Dr. Copeland's measures of the bright parts in Nova Orionis did not exactly agree with laboratory determinations of the wave-lengths of the hydro-carbon bands. He does not, however, make mention of the fact that there are two perfectly distinct sets of bands seen under different conditions. Nor does he refer to the "laboratory work" which has been relied on to show that they are not hydro-carbon bands at all. The mean of Dr. Copeland's measures of the bright line in the green, beginning a band, is 516·2. The wave-length of the first carbon fluting of one series is given by Thalén as 516·4, which, therefore, gives a difference of 0·002 in the two determinations. The line measured by Dr. Copeland at 513·7 is said by Mr. Maunder scarcely to support his view, since the second maximum of the carbon fluting has a wave-length 512·8, and of the blue carbon fluting it is noted, "The third hydro-carbon band, that in the blue with wave-length for its less refrangible edge 473·7, is indeed not far from the bright space Dr. Copeland has observed at λ 472·2, but the correspondence is certainly not very exact." Since this criticism was made, however, it has been shown that at different temperatures the maximum of the blue carbon fluting may shift from 468 to 474, so that Dr. Copeland's measures may represent the exact position of the band in the Nova.

But it is evident that a vast difference must exist between the accuracy attainable in the observatory and in the laboratory. Dr. Copeland's measures appear to give the smallest probable error in the determination of wave-lengths in such an object as Nova Orionis, yet he measured the brightest band once at 517·4 and on the following evening at 515·6, a difference of 0·018. The difference of the observations *inter se* exceeds any of the differences between the bright parts measured by Dr. Copeland and the accepted wave-lengths of the carbon bands; nevertheless Mr. Maunder says the observations are "undoubtedly very accurate," hence it cannot reasonably be argued that the bright bands are not carbon because of a want of exact coincidence with those measured in the laboratory.

Mr. Maunder also notes that "the second band in order of brightness in the hydro-carbon spectrum begins at λ 563·4. This is certainly non-existent in spectra of the third type; a broad dark band—No. 4 in Dunér's nomenclature and my own, wave-length 564·2 to 559·2—occupies the very place." This contention, however, is no longer allowable, since the recent researches show that the carbon fluting of one series at 563·4 is masked by the

[1] *Comptes rendus*, vol. cii. p. 356, 1886.
[2] *Monthly Notices R.A.S.*, xlvi. p. 284.

absorption of the first manganese fluting at 557·6, and the same argument might be employed to abolish carbon from many cometary spectra.

My recent work has entirely justified Dr. Copeland's observations, and to him certainly belongs the credit of having established the existence of the carbon bands bright in a new star.

J. NORMAN LOCKYER.

ON THE SOARING OF BIRDS.

THE interesting problem of the soaring of birds, though repeatedly discussed, especially in NATURE, has not yet found a satisfactory solution. This is the explanation I propose.

Suppose that a bird soaring horizontally with a certain velocity enters a current of air cutting his own course rectangularly. The bird will be seized and partly borne by the wind. Instead of passing by calm the distance *a* to *b*, he will advance from *a* to *c* in the same space of time (see Fig. 1; the arrow *ef* indicating the direction of

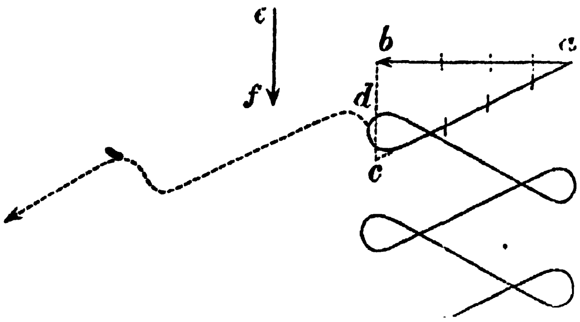

FIG. 1.

the wind, and the cross-lines the length-axis of the wing-area). The way *a* to *c* evidently being longer than *a* to *b*, the bird, on arriving at *c*, has a greater absolute velocity than if he had pursued, in a calm, his course *a* to *b*. It is equally evident that, if the initial velocity of the bird and the velocity of the wind are properly adapted, the velocity of the bird at the point *c* can, in spite of the resistance of the air to his advancing, be greater than at *a*. If arriving at *c* the bird can turn against the wind[1] without considerable loss of velocity, it is clear that he is able to continue his new course for a short space, before his velocity sinks to the initial velocity which he possessed at the point *a*. During this part of his course, the relative velocity of the bird (with relation to the air) is more than twice the absolute velocity of the wind, supposing the initial velocity of the bird equal or superior to that of the wind. Let *d* be the point where the absolute velocity of the bird has sunk to the initial velocity. If the bird turns at *d*, so that his course crosses the direction of the wind at right angles, he is again ready to begin the same course as when starting from *a*. Thus, on the way *a* to *c* the absolute velocity increases, on *c* to *d* it diminishes as much.

Let us now suppose the direction of the wing-plane unchanged: the course of the bird will no longer lie in the horizontal plane, but, from reasons now easily understood, *a* to *c* will gradually drop down to the earth, according as the relative velocity diminishes; on the other hand, *c* to *d* will rise according to the increment of the relative velocity. Which will be the greater, the sinking or the rising, depends on several circumstances, but principally on the force of the wind, the adaptation of the wing-plane, the size and form of the bird and the corresponding proportions between the bearing of the wings and the resistance of the air. This resistance is, of course, in proportion to the weight, less to the advancing of large birds than to the advancing of small birds. This is the reason why large and heavy birds are the best soarers.

It results from this that a bird suitably built for the purpose can not only maintain the same level without working his wings, by a uniform and moderate wind, but also gain in height by adroit movements.

It may perhaps be objected that, according to this scheme, the course of the bird will not be spiral, but run in figures of eights gradually moving in the direction of the wind or in continuous windings on the one or on the other side and partly with the wind (Fig. 1). Indeed it is likely that the movements of the birds will often prove that they profit by this principle in manœuvres the purpose of which has not yet been understood.

The spiral soaring is still to be explained. I think we must suppose that commodiousness is the principal motive thereof. Let us fancy that a bird, having acquired the necessary initial velocity, soars in a calm without working his wings, not in a rectilinear course, but by suitable inclinations and turnings of the wings in circular courses. We know that, in order to perform this manœuvre, the bird drops the interior wing a little and raises the exterior wing just as much, so that the wing-plane, during this motion, forms a conic ring, the top of the cone pointing downwards. If the velocity did not diminish, the bird would be able to continue this course indefinitely, or he would rise or sink in a screw-formed course, according as the velocity should increase or diminish. By greater inclination of the wing-plane to the axis of the cône, the circles would become narrower; by diminishing inclination, they would become wider: both these motions are easily produced by minimal changes of the form of the wing-plane or of the place of the centre of gravity. Let us further suppose that the stratum in which the bird soars is continually moving in a certain direction. From the moment the course of the bird is perpendicular to the direction of the wind (point *a* in Fig. 2) till the moment

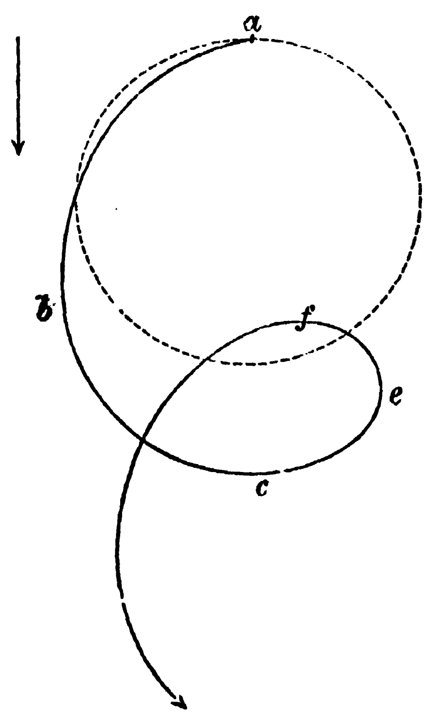

FIG. 2.

it grows parallel with it (*b*), the bird obtains from the wind an addition to his absolute velocity (not considering the loss occasioned by the resistance of the air) and also an increment of velocity from the moment his course deviates from the direction of the wind (*b*) till the moment it grows perpendicular to it (*c*). From this moment again the absolute velocity gradually diminishes, till, at last, at the point *f*, it reaches its minimum. From this point (*f*),

[1] It has long been acknowledged that some birds possess the power of changing their direction without any sensible loss of velocity.

a new circle begins identical with the first one, if the absolute velocity in *f* is the same as that in *a*, which does not imply any impossibility, even including the resistance of the air to the advancing. It is, however, important that the increment of velocity during the course *a–b–c*, is equal to its diminishing during the course *c–e–f*. Certainly the resistance of the air caused by the wind is greater during the latter part of the course than during the former, but the way is shorter in which this greater resistance is working.

In which plane or in which planes the different parts of the course will pass depends upon the initial velocity and upon the changes of the relative velocity of the bird; naturally also upon the invariable quantities—the weight of the bird, the size and form of the wing-plane, so far as the latter has influence upon the resistance of the air to the advancing. Now in *a* and *f* the relative velocity is the same as the absolute or minimal velocity. In *c* the relative velocity is also the same as the absolute velocity, but in *c* they are both greater than in *a* and *f*, as we have shown here above. Thus the relative velocity has increased during the course *a–b–c*. During the course *a* to *b* no increment has occurred, on the contrary; so much the faster has it increased during the course *b* to *c*. During the course *c* to *e* the relative velocity increases continually, and obtains near *e* its maximum; whereas it gradually diminishes during the course *e* to *f*, so as to equal the initial velocity. Suppose then that the relative velocity diminishes somewhat during the course *a* to *b*. This diminution, however, will be over-compensated during the course *b* to *c*, the relative velocity in *c* being greater than that in *a*. During the whole course *c–e–f*, the relative velocity is greater than in *a* and *f*. Surely the supporting power of the current of air on the wings depends upon the relative velocity. It increases with the relative velocity, if we suppose everything else to be unchanged, particularly the angle of inclination of the wing-plane. If, therefore, the initial velocity in *a* by a certain pointing of the wing-plane is only just sufficient to maintain the bird at an unchanged level, the bird must, when describing the course *a* to *b*, gradually drop down. Even on the other side of *b* the sinking is continued until the relative velocity has increased so as to regain the same value as in *a*. From this point the course begins to rise and will continue rising until *f*, for to this point the relative velocity is greater than in *a*. Under such circumstances we cannot be astonished if the part *f* of the course will be in a higher plane than the part *a*, even if the resistance of the air to the advancing is infinitesimal.

Should the initial velocity in *a* be greater than what is required to maintain the bird on the same level, the bird would already there have a rising course, and it might easily happen that no part of the course would be descending. However, the resistance of the air increases much faster than the relative velocity, and therefore the most available initial velocity will be different for different birds and for different force of the wind. It is not as yet an easy matter to calculate the most favourable initial velocity to certain birds and to certain winds. But the discrepancies in the descriptions of the forms of the circles find, as may easily be seen, their explanation in supposing a different initial velocity. This is likely to be chosen differently by different birds, and may be different for the same bird according to different force of wind.

I am convinced that the bird always, even when soaring with the wind, has a greater velocity than the wind, and that thus during this part of the circle his speed is not hastened by the wind, but on the contrary he is here delayed, maybe less than in the other parts of the course. On the other hand, the velocity of the bird is augmented by the wind, as soon as the wind catches the bird from the side or obliquely from behind. This gain of velocity covers the loss caused by the resistance of the air to the advancing, and consequently allows the bird to maintain the necessary average velocity. It is less obvious, but nevertheless very likely, that the soaring bird, having gained the necessary velocity and having pointed his wings suitably, can, without changing the form of his wings, incessantly continue the soaring, as long as the force of the wind is unchanged.

Mr. Peal's [1] explanation no doubt comes nearest the truth, when he compares the soaring bird to a kite. We may consider the bird a kite, but the string which connects him with the earth is not fixed at a point of the surface of the earth, but the point of fastening moves with the wind, though it may be slower than the wind. It is the difference of velocity between the motion of the fastening-point and that of the air which affords the necessary power for the support and the rising of the bird. MAGNUS BLIX.

Lund, Sweden.

ELECTROLYSIS OF ANIMAL TISSUES.

A PRELIMINARY account of part of the work was given in the Proc. Roy. Soc. Edin., 1888, and a short description of later results at a meeting of the Physiological Society at Cambridge in March last. The full paper is being published in a volume of memoirs from the physiological laboratory of the Owens College, Manchester. The chief results are here summarized.

(1) The first part of the research was directed to answering two questions: (*a*) *Is the conduction in animal tissues entirely or chiefly electrolytic?* (*b*) *What are the electrolytes?* It is shown that by far the greatest part of the conduction at any rate is electrolytic, and that the best conductors by far are the inorganic constituents of the tissues. Next to these, but at a great distance, come some of the nitrogenous metabolites. The proteids are exceedingly bad conductors.

(2) *The changes produced in simple proteid solutions* were next investigated. It is shown that the proteids are affected not by primary electrolysis, but by the products of electrolysis of the salts.

The effects vary to some extent with the current density. In solutions of coagulable proteids alkali-albumin is formed at the cathode, and acid-albumin at the anode, some of the proteid being coagulated at the latter.

(3) *The effects of electrolysis on isolated tissues and on some of the liquids of the animal body.*

Striped Muscle.—Great changes were found in the microscopic appearance of the fibres. The nuclei became very prominent in those near the anode, with apparent coagulation of the sarcous substance, suggesting the action of a dilute acid. At the cathode the fibres were more homogeneous than before. The striation was impaired. Chemically, the same changes in the proteids were found as in simple proteid solutions, and a distinct effect on the distribution of the salts was made out, by estimating the ash in different parts of the muscle.

Blood.—Entire defibrinated blood, blood serum, and pure hæmoglobin solutions were used. There was no indication that hæmoglobin, or any derivative of it, acts the part of an ion. At the anode the reaction becomes acid, and acid-hæmatin is formed, which remains partly in solution and is partly thrown down, the solution becoming less deeply coloured. When the current is strong or long continued the hæmatin suffers further change and is decolorized, apparently by the oxygen or chlorine set free. If a reducing agent is present at the anode, the hæmoglobin there is not affected by the electrolysis. At the cathode alkali-hæmatin is ultimately formed, although its less definite spectrum does not show itself so soon as that of acid-hæmatin at the anode. The proteids of the serum and corpuscles are

[1] NATURE, vol. xxiii. p. 10.

partly coagulated at the positive pole. At the cathode they are partly changed into alkali-albumin.

Bile and urine were taken as further examples of animal liquids.

(4) *The effect of electrolysis in the living body.*

Pithed frogs and anæsthetized rabbits were used. This part of the work is still incomplete.

G. N. STEWART.

LOBSTER CULTURE IN THE ISLE OF MULL.

WE have been favoured with a circular, issued by Mr. George Brook, Lecturer on Embryology in the University of Edinburgh, and Mr. W. L. Calderwood, late of the scientific staff of the Fishery Board for Scotland, expressive of an intentention to establish at Lochbuie a small marine laboratory. The promoters have set themselves to restore our shell fisheries to their former condition; and a leading item in their programme is the proposal to construct a lobster pond, with suitable apparatus for hatching and rearing lobsters. The cost of the entire laboratory, with pond and plant, is estimated at £400, that of maintenance at £150 per annum—exceedingly moderate sums, for which an appeal is made to the public. The condition into which our lobster fisheries have lapsed is shown by the fact that a lobster ground in the far west of Ireland is worked by a South of England boat. Our import lobster trade is yearly increasing, and the fact that our markets are not home-stocked is discreditable in the extreme. The problem of artificial culture necessary for the purpose in view has many times been attacked by British naturalists. Saville Kent had it constantly in mind while officiating at our several aquaria; he made it a primary object in his schemes for the establishment of marine stations in Jersey and at Brighton, and he meanwhile attempted to raise interest in it in a paper read at the International Fisheries Exhibition held at South Kensington. All this notwithstanding, the matter has, with us, not yet passed beyond the experimental stage, and we are behind in the international race. At Lochbuie the conditions should be favourable; and as Mr. Brook, in the preparation of his *Challenger* Report, has shown himself capable of performing a difficult task under exceptional conditions, we have full confidence in his ability to carry out his project. The promoters of this scheme propose in other respects to pursue a course of scientific study of the marine fauna of the west coast of Scotland, but their chief aims are unmistakably economic. We sincerely hope that they will confine their attention to the one or the other branch, for nothing can be plainer than that the extraordinary successes which have placed the fishery work of our American cousins foremost in that of the world, have been largely, if not wholly, due to their having kept pure science and economics scrupulously apart. The Lochbuie scheme is a modest though an ambitious one, and Messrs. Brook and Calderwood signify their intention of giving their services as superintendents. Recent proceedings in Parliament have shown that there is disaffection on the Scottish Fishery Board; and it would be an interesting circumstance should private enterprise, which has done so much for science in Britain, solve the difficulty in hand, while the State-aided body fritters away a handsome endowment.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE nineteenth meeting of the French Association for the Advancement of Science opened at Limoges on the 7th inst.

After some remarks on the learned societies of Limoges, and some references to Gay-Lussac, the inauguration of whose statue took place on the 11th inst., Prof. A. Cornu, the President of the Association for the year, delivered a discourse on the part played by physics in the progress of the sciences. It is impossible in the space at our disposal to do justice to this interesting address, but the following will give an idea of its character.

Beginning with chemistry, Prof. Cornu pointed out that the introduction and use of the chemical balance by Richter, Wenzel, Dalton, and Lavoisier led to the substitution of the laws of multiple and equivalent proportions, and the indestructibility of matter, for the vague hypotheses held by the alchemists.

Two other physical instruments introduced into chemical methods are the calorimeter and barometer. By means of the first, Dulong and Petit's law, that the same quantity of heat is required to heat an atom of all simple bodies to the same extent, was discovered; and but for the second, Gay-Lussac could not have made his researches on vapour density, which, with the work of Ampère and Avogadro, led to the determination of the numerical relation between the temperature density and pressure of a gas and the notion of atomic volume.

Another common physical instrument, the thermometer, has furnished organic chemistry with the means of discovering important laws of organic series; and recently, with the calorimeter, it has enabled M. Rault to determine molecular weights by the freezing of dissolvents, and has furnished Thomson, Berthelot, Sarrau, Vielle, and other workers in thermo-chemistry with the means of arriving at the new mechanics of the affinity of atoms according to their size, like the universal law of gravitation.

The introduction of the spectroscope into the chemical laboratory for purposes of analysis, by Bunsen and Kirchoff, marks an important epoch in the history of chemistry. This instrument has been entirely created by the labours of physicists; the prism of Newton, the telescope of Fraunhofer, and the collimator of Babinet marking stages in its evolution Bunsen and Kirchoff demonstrated the power of their method of analysis by the discovery of rubidium and cæsium; in fact, it is only necessary to observe an unknown line in the spectrum of a substance to establish the existence of a new element.

It appears therefore that each time chemistry has borrowed from physics some new method it has entered into a prolific field of investigation, conceptions have been extended and given a more precise meaning, and chemical knowledge advanced in a manner proportional to the power of the adopted methods.

The other natural sciences have benefited in the same way. Up to the seventeenth century astronomers had no means of assisting their vision, and therefore they could only make observations of the movements of the heavenly bodies. In spite, however, of the simplicity of the means of observation, the work of Hipparchus, Ptolemy, Copernicus, Tycho-Brahé, and Kepler contained a considerable amount of information with respect to celestial motions, but nothing was known of the constitution of the bodies observed. With the refracting telescope of Galileo and Newton's reflector, astronomy underwent a transformation: the sun was found to have spots and faculæ; the plains, mountains, and craters of the moon were observed: Venus was shown to go through phases in the same manner as our satellite; Jupiter's belts and satellites were seen; and the beauty of Saturn and his rings revealed.

Later, Herschel's large mirrors, worked by his own hands, enabled him to discover double and multiple star systems; to prove that many stars are suns like our own, inasmuch as they have other bodies revolving round them.

Such was the revolution produced in astronomy by the employment of the first optical instruments. The intro-

duction of the spectroscope considerably extended the limits of investigation. The chemical constitution of the stars was determined in spite of their immense distances; the sun was shown to contain sodium, iron, magnesium, calcium, hydrogen, in a state of vapour at its surface—that is, the same elements as those which make up the earth's crust; it also contains nickel, an important constituent of meteorites, those nomadic bodies which fill interplanetary space. The sun and the bodies revolving round it are therefore composed of the same elements.

By means of the spectroscope it has been proved that the moon and the planets shine by reflected light, and that the stars, like the sun, are self-luminous, and made up of the same elements, thus demonstrating the unity of the chemical composition of the whole universe.

But the spectroscope has not only revealed the substance of the stellar world, it affords a means of investigating a component of stellar motion. The principle enunciated by Doppler, viz. that light-waves, like those of sound, vary in length with the relative velocity of the source producing it, remained unapplied for some time because there was, of course, no means of determining the proper colour of a star in repose and comparing it with that received, the variation being produced by motion in the line of sight. Fizeau showed, however, that by substituting lines in the spectrum for the idea of colour the conditions necessary for the application of the principle were met; all that was required being a line common to a star and some terrestrial element, and the measurement of the displacement of this line. This method was proposed by Fizeau in 1859, and has been considerably developed; numerous lines in stellar spectra are coincident with those of terrestrial substances. If they are all shifted towards the red the star is receding from the earth; if towards the violet the star is approaching us. The displacement of the line is measured with a micrometer, and a simple calculation gives the velocity with which the star is moving, whatever may be its distance.

It has been shown that for the application of the Doppler-Fizeau principle it is necessary to find in the spectrum of the star the lines of a terrestrial element. This common element is most often hydrogen—the simple body *par excellence*, the elementary substance of those who hold in the unity of matter.

Among all the methods of rendering impurities manifest, the simplest and most delicate is that of spectrum analysis. With the spectrum of hydrogen observed in the laboratory feeble lines of other substances are always present, and to decide upon the true hydrogen spectrum becomes therefore a difficult matter. But it was an astronomer and not a chemist who first described the pure hydrogen spectrum; the lines photographed by Dr. Huggins in the spectra of the white stars having since been shown to be reproduced in the laboratory when the spectrum of approximately pure hydrogen is observed.

In physics, the centre of natural philosophy, many branches have made rapid and definite advances. The results of the development of electrical science is seen on all sides, yet no science has had a more humble beginning. The first electrical experiment was made six centuries before our era: this was the attraction of light bodies by rubbed amber. The knowledge remained in this stage for more than twenty centuries; then the two electrical states were gradually recognized, and conductors and non-conductors were separated. In the establishment of the identity of atmospheric electricity with that obtained by electrical machines the death of Richmann at St. Petersburg should be noticed, and the discovery of the lightning conductor by the illustrious Franklin.

Everyone knows the story of the convulsive movements of a frog's leg in contact with a bimetallic arc observed by Galvani, an Italian physiologist. Volta saw in this circumstance that electricity might be developed by the contact of different substances; he discovered the law which permitted the energy to be multiplied; and in 1794 summed up all his works in an imperishable monument—the voltaic pile.

All the sciences benefited by the discovery, but chemistry gained the most. Carlisle and Nicholson decomposed water; Davy, with the great pile belonging to the Royal Institution of London, decomposed the alkalies and alkaline earths, formerly supposed elementary bodies. Later, Davy performed an experiment which eclipsed everything accomplished with the invention of Volta. By joining two carbon poles to his colossal pile, he produced a dazzling and continuous light, and discovered the electric arc now so commonly seen.

In 1820, Oersted discovered that the wire joining the poles of a pile exercised an influence on a magnetic needle. Ampère discovered the mutual action of electric currents, the mathematical law governing it, and, finally, the production of magnetism by the sole action of the voltaic current.

The discovery of the electro-magnet was a great event, not only in the history of science, but in that of humanity. In telegraphy it is the electro-magnet which transmits messages from one end of the world to the other with the velocity of light; in the telephone, the word itself; in the powerful machines derived from the memorable discoveries of Faraday, it is that which causes the transformation of energy.

Great advancements have also been made on the purely theoretical side. Ampère, Poisson, Fourier, Ohm, Gauss, Helmholtz, Thomson, and Maxwell have done much to connect electricity with mechanical laws. Again, electro-magnetic and optical phenomena obey the same elementary laws, and appear to be two manifestations of the movement of the same medium—the ether; thus optical problems may be settled with the equations of electro-magnetism. From an experimental point of view, results full of promise have already been obtained; the velocity of light, found by optical methods, has also been determined by measures purely electrical; and recently M. Hertz has accomplished experimentally the identification of electrical discharges with light-waves.

All these facts show that as our knowledge increases the distinctions between different branches of science vanish; the limits which have been traced between them are shown to be artificial, and only testify to ignorance of natural laws; but the efforts of successive generations have not been in vain, and we look forward to the time when these limits will be effaced, and all the branches of natural philosophy be united in one harmonious whole.

Prof. Cornu's discourse, of which the foregoing is but a sketch, was received with much applause.

After an address by the Mayor of Limoges, the Secretary of the Association, M. A. Gobin, read the report for 1889-90, and gave an account of the meeting in Paris last year. The financial statement by M. Gallante shows that the Association is in a prosperous condition, and increasing its number of members.

Many interesting and important communications were made in the different sections. The series of excursions included one of three days' duration, and visits were made to all places of interest in or near Limoges. The Congress will be remembered as a very successful one by all who were fortunate enough to be present.

C. H. F. PETERS.

BY the death of Prof. C. H. F. Peters, Director of the Litchfield Observatory, Hamilton College, Clinton, N.Y., astronomy has lost an assiduous observer. An interesting sketch of his career is given in the *Astronomische Nachrichten*, from which the following details are taken.

He was born at Coldenbüttel, in Schleswig, on Sept. 19, 1813, and educated at the Gymnasium of Flensburg and the University of Berlin, where he studied mathematics and astronomy. Having taken his degree in 1836, he tried to obtain an appointment at the Observatory of Copenhagen, but his application was not successful. He then went to Göttingen, to carry on his studies under Gauss. Afterwards he was induced to undertake some scientific investigations relating to Mount Etna.

Having accomplished the task entrusted to him, he was made Director of the Trigonometrical Survey of Sicily. Of this appointment he was deprived in 1848, when he gave great offence to the authorities by expressing sympathy with the revolutionary party. He escaped on board an English vessel to Malta, but soon returned to Sicily, and joined the Sicilian army under Mieroslawski, acting first as a captain, then as a major, in the engineering branch of the service. It was under his direction that Catania and Messina were fortified. When Palermo fell into the hands of the Neapolitans, in May 1849, he fled to France, but soon changed his residence to Constantinople, where he proposed to devote himself in peace to scientific research. Here he secured many friends, and it was intended that a scientific expedition, under the guidance of Peters, should be sent to Syria and Palestine. Various obstacles, however, stood in the way; and the scheme had to be given up after the outbreak of the Crimean War.

He now turned his attention to the United States; and, with recommendations from Alexander von Humboldt, he went in 1854 to Cambridge, Mass., and from thence to Washington, where he obtained an appointment on the Coast Survey. After working for some time in this position, and establishing an observatory at Utica, he accepted, in 1858, the offices of Director of the observatory at Clinton, N.Y. (now known as the Litchfield Observatory), and Professor of Astronomy at the Hamilton College. The duties of these offices he continued to discharge until his death, which took place on the morning of July 19. He was found dead on the road between the observatory and his house, and seems to have died of heart-disease when returning from his work.

In 1874 Peters acted as chief of the North-American Expedition to New Zealand for the observation of the transit of Venus. He discovered no fewer than 48 minor planets and several comets, and much important work was done at Hamilton College under his supervision, his celestial charts and star catalogue being of considerable value. Few astronomers leave a better record behind them, and his death is much regretted.

NOTES.

THE annual excursion of the Belgian Royal Malacological Society took place under the guidance of MM. X. Stainier and J. S. Gardner. The Eocenes from the Thanets to the Lower Bagshots were examined at Herne Bay and Sheppey, where Mr. Shrubsole assisted, and the Gault and Chalk at Dover and Folkestone. The Eocenes seen were pronounced to be in all respects identical with beds of corresponding age in Belgium. The Society proposes to revisit England next year.

AMONG the excursions which have been arranged by the Local Committee of the British Association is one to Malham in Craven. This is to take place on Thursday, September 11, under the guidance of the officers of the Yorkshire Naturalists' Union. The district to be investigated is the plateau of Malham and the escarpment which it forms along the South Craven fault. It includes the only lake in the West Riding, and the remarkably picturesque scenery of Malham and Yoredale. In addition to these attractions, every branch of natural history can be successfully pursued in this locality. This advantage arises chiefly from the diversified character of the geological formations, which include Silurian rocks, mountain limestone, Yoredale shales, and millstone grits. We believe that this will be a popular excursion among members of Field Naturalists' Clubs, who will have an opportunity of observing the methods of work adopted by the Yorkshire Naturalists' Union, and it is hoped that as this will be an essentially working excursion, any field naturalists and geologists who may take part in the Leeds meeting of the British Association will attend the Malham excursion.

WE learn that the French physicians who went to the International Medical Congress at Berlin were much gratified by the cordiality with which they were received.

IN a letter to the *Times* the other day, Mr. John Cordeaux referred to a unique collection of migrating birds formed at Heligoland by Herr Gätke as the result of work carried on during 40 years. This collection, he added, was to be brought to England, "having been secured to the nation by the munificence of a single individual." With reference to this statement, Prof. W. H. Flower writes from the British Museum (Natural History), Cromwell Road, to the *Times* as follows:—"May I supplement the letter of Mr. Cordeaux by saying that the individual by whose liberality Herr Gätke's collection has been secured for the nation is Mr. Henry Seebohm, and that arrangements are being made by which, when the collection arrives, it will be permanently exhibited in this Museum?"

A WORK on "The Birds of the Japanese Empire," by Mr. Henry Seebohm, is nearly ready for publication. It is illustrated with numerous woodcuts. Mr. R. H. Porter is the publisher. The same publisher has in the press "The Birds of Sussex," by Mr. William Borrer. This work is supplied with a map of Sussex, and with six coloured plates by J. G. Keulemans.

MESSRS. MACMILLAN AND CO. announce for publication this week an English translation of Prof. Ostwald's "Grundriss der allgemeinen Chemie" by Dr. J. Walker, of Edinburgh University. This work covers the same ground as the author's classical "Lehrbuch," but the treatment throughout is elementary, and, as far as possible, non-mathematical. The new modes of molecular-weight determination, van 't Hoff's theory of osmotic pressure, Arrhenius's hypothesis of electrolytic dissociation, and the interesting applications of these to purely chemical problems—all receive special attention at the hands of the author. The appearance of the book is particularly well-timed, as we learn that Profs. Ostwald, Raoult, van 't Hoff, and Dr. Arrhenius have intimated their acceptance of the invitation issued to them by the British Association, and will be present at the coming meeting in Leeds.

THE first volume of a work by Prof. A. de Mortillet, on the origin of hunting, fishing, and agricultural pursuits among primitive races, has just been published. It contains many interesting representations of prehistoric implements in the Saint Germain Museum.

ATTENTION has been called in various quarters (England, Belgium, France, and Germany) to the remarkably cold weather prevailing of late years, since 1885, in Central and Western Europe; the yearly averages being constantly under the normal. It now appears from an Algerian record, that these years have been warmer than usual in Algeria. It is also shown that there has been no change in the frequency of north and south winds, while in Europe the north-east winds have been increasing in frequency.

IN the new number of the Journal of the Anthropological Institute the most elaborate paper is one on the Dieri and other

kindred tribes of Central Australia, by Mr. A. W. Howitt. There are also papers on characteristic survivals of the Celts in Hampshire, by Mr. T. W. Shore; skulls dredged from the Thames in the neighbourhood of Kew, by Dr. J. G. Garson; and a new spirometer, by Mr. W. F. Stanley. In the paper on Celtic survivals in Hampshire, Mr. Shore refers to the feeling with which the May-day sunrise was regarded by the ancient Celts. "This May-day sunrise," he says, "was certainly reverenced in mediæval Christian time as well as in pagan Celtic time, for the line of about 20° north of east is the line of orientation of a large number of the oldest churches in Hampshire, and of many in other counties. It is a common orientation among the oldest churches of Hampshire, in which county there are as many as seventy examples of it. I cannot explain this on any other ground than the survival of a reverence for the May-day sunrise from Celtic pagan time to Saxon Christian time, and under a modification to a later date. It appears to me that, as there is evidence of the survival of part of the Celtic people, it is not surprising to find that traces of their May-day customs have survived also. It is of course possible that in this common line of orientation of many old churches we may see all that remains of one of the customs of the old British Christianity which existed before the coming of the Saxons."

ACCORDING to the *Journal de la Chambre de Commerce de Constantinople*, quoted by the *Board of Trade Journal*, the silk section of the Agricultural Society of Moscow has offered a prize of 500 roubles for the best work on the anatomy and embryology of the silkworm. Works on this question must be sent not later than January 1, 1892.

THE Rio Negro Salt Company seems to have had an interesting stall at the Rural Exhibition recently held at Palermo, near Buenos Ayres city. The Buenos Ayres *Standard*, in an article quoted by the *Board of Trade Journal*, thus calls attention to the subject:—"Here, in an unpretending but exhaustive manner, are displayed the products of those vast *salinas* or salt lakes which lie some few miles north of the town of Patagones, and which this company has recently commenced to work. There are large blocks composed of big crystals taken in the rough from the *salinas*; barrels of natural brine; compressed cakes for cattle; coarse salt for hides and meat curing; ground salt for kitchen use; and refined salt, dazzling as snow, and in every way equal to the English bottled salt, for use at the domestic table; in short, salt in every form that can be desired either for practical wants or the dainty demands of luxury. Pamphlets are distributed containing analyses by eminent men of science, which demonstrate the excellence and purity of its quality, and its adaptability for all known purposes. As regards quantity, we were informed that a calculation had been made that in a given year it would be possible to take from the Rio Negro lakes, occupying an extension of about nine square leagues, upwards of two millions of tons, and that, in the ensuing season an equal quantity of salt would be found, owing to the fact that every winter the lakes became filled with a brine of a density of from 25° to 32°, which in due time becomes a solid cake of salt."

A *Zeitschrift für Psychologie und Physiologie der Sinnesorgane* (*i.e.* organs of sense), has been recently started in Germany (April), under the editorship of Herren Ebbinghaus and König, the former of whom is known for some remarkable researches on the memory, and the latter for his studies in physiological optics. Among the contributors are Herren Aubert, Exner, Helmholtz, Hering, and other eminent men of science. The following are some of the subjects that have been dealt with: disturbance of the perception of very small differences of brightness by the proper light of the retina: simultaneous contrast; disappearance of after-images in eye-movements; memory of regularly successive and equal sound-impressions.

IN the *Victorian Naturalist* for June, Mr. G. Lyell, Jun., of South Melbourne, notes that while walking along the edge of a mountain stream in Gippsland last January he observed a peculiar habit of the Victorian butterfly, *Papilio macleayanus*. One of these butterflies was seen to alight close to the water, into which it backed till the whole of the body and the lower part of the hind wings were submerged, the two forelegs alone retaining their hold of the dry land. After remaining in this position for something like half a minute it flew away, apparently refreshed. "During the morning," says Mr. Lyell, "I noticed quite a number doing the same thing. In one instance no less than four were to be seen within a space of not more than three yards, and to make sure that I was not deceived I captured several as they rose from the water, and found in each case the body and lower edge of the hind wings quite wet. While in the water the fluttering of the wings, so noticeable at other times, was suspended, and so intent were the butterflies in the enjoyment of their cold bath that they would hardly move, even when actually touched by the net. Apparently the heat of the weather drove them down to the water, as immediately they emerged they flew up again to the hill-sides. I have often noticed butterflies of the *Nymphalidæ* family settling near the pools, and apparently imbibing the moisture from the damp sand round the edges, but never before have I seen butterflies enter the water. Possibly it may be a peculiar habit of this particular species or genus. Numbers of the white butterfly, *Pieris harpalyce*, were flying about at the same time, but I noticed none alight near the water."

SOME interesting observations on the growth of vegetation in the numerous lakes to the east of the Baltic have been lately made by Herr Klinge (*Engler's Bot. Jahrb.*). This growth depends on the mean direction of the wind during the period of vegetation. As south-west winds prevail in that region, the south-west border of a lake is protected, and the grassy and mossy growth naturally begins there, and spreads by degrees round the north and south ends. The north-east bank, on which break the waves from the south-west, shows hardly any trace of vegetation. It is generally steep, and tends to retire under the action of the waves. Something similar is met with in the Baltic: shore-meadows occur in the islands only on the east, wind-protected coasts. Further, rivers are displaced in the direction of the prevailing winds, eating away their eastern banks, while the western grow. The dead arms of the lower Embach are, with few exceptions, on the south side of the river, which, under the action of the wind, has been displaced northwards, *i.e.* (with reference to its direction) to the left, and so, contrary to Baer's law of river-courses. Indeed, the author rejects this law, and holds the principle of displacement according to prevailing winds to be universal. It is noteworthy that this relation has of late been pointed out by several Continental observers independently. Herr Klinge further finds that in the region east of the Baltic, hygrophilous (or moisture-loving) plants grow on the south-west side of the hills, and xerophilous plants on the north-east side.

THE Märjelen Lake, which lies in Upper Valais, lately burst the glacier dam which lay across the valley. According to the Swiss *Vaterland*, a peasant who was close to the lake at the time declares the scene was most terrible and indescribable. When the ice dam gave way, the vast mass of water came tumbling out, sweeping away the huge fragments of the glacier, with the rocks upon it, tumbling into the crevasses, bursting them up in turn, and rising over the glacier in gigantic waves, again to carry all before it. Just at the end of the glacier the valley had narrowed into a little defile,

while the face of the glacier was some hundreds of feet high. The water seemed to have tunnelled under the ice, which, attacked above and below, gave way at last with a deafening crash, while the flood hurried down the mountain-side into the Rhone. The lake is nearly 8000 feet above the sea-level, and usually discharges its surplus water by subterranean channels, occasionally bursting its ice barriers as on the present occasion. The cantonal Government are constructing an overflow canal, which, it is hoped, will put an end to these periodical outbursts.

IN a paper printed in the new number of the Transactions and Proceedings of the New Zealand Institute, Mr. Taylor White describes an extraordinary meteor which he saw at Wimbledon, Hawke's Bay, on May 4, 1888, between 8 and 9 o'clock p.m. The nucleus, or head, was of oval form, of a transparent light-yellow colour, as of iron at a white heat. The tail was in the form of the tail of a pheasant, expanded—that is, the two centre streamers were of uniform length, the outer ones gradually shortening, so that the outermost streamer on either side was very much shorter than those in the middle. These streamers were of a dull, opaque orange. They were distinctly divided each from each by dark bands, which consisted of several fine black lines, to, probably, the number of five in each band. Mr. White is unable to fix the number of orange streamers, but would guess ten as probably correct. The colours blue and green were also certainly present. No sound was audible while the meteor was in view. "But," says Mr. White, "after I had gone into the house, and was describing what I had seen, the sound of its striking the earth or sea was heard—a loud and lengthened noise, to me like the violent shaking of all the forest trees, and evidently above ground, thereby differing from the sound accompanying an earthquake—coming from the westward; and this was followed, after a hardly perceptible interval, by a fainter sound, like an echo, to the north-east. The time which elapsed till the sound was heard was from three to five minutes." Various New Zealand daily journals gave full descriptions of the phenomenon at the time. According to the *New Zealand Times*, the apparent size of the meteor was "quite half that of the full moon."

THE editor of the Journal of the Royal Agricultural and Commercial Society of British Guiana contributes to the June number some interesting notes on luminous larvæ. Speaking of a form referable to the *Elateridæ*, or spring beetles, he says its luminosity, when observed in a dark place, is singularly striking and beautiful. The light is emitted along the whole length of the body—the head, the front part of the anterior segment, and the last segment of the body, being altogether luminous, while each intermediate segment gleams from a small area on each side of the back, two regularly-arranged rows of golden brilliants being thus observable. The light is continuous, and very bright, but it is intensified when the little creature is irritated. At intervals, one or more of the dorsal lights will be observed to be very dull or nearly extinguished, but apparently they are never quite put out.

MR. T. D. LATOUCHE, who contributes to the Records of the Geological Survey of India a paper on the sapphire-mines of Kashmir, takes the opportunity to offer some remarks on the extent to which the natives of India know the mineral resources of their country. He thinks he is not far wrong in saying that in very few instances in India have useful minerals been discovered in localities that were unknown to the natives, and in which the ores had not been worked by them at one time or another. Even the more uncivilized hill tribes are more or less well acquainted with the minerals their hills contain, and are by no means in the condition of the Blacks of Australia or the Bushmen of Southern Africa, in whose country the European prospector has found so great a field for his energies. To take a single instance: the Khasis of Assam, who, till the beginning of the present century, had hardly felt the influence of Western civilization, have for ages obtained their iron from an ore which occurs as minute grains of magnetite disseminated in the granite of their hills. Many a highly-trained European geologist might justly have been sceptical as to the possibility of obtaining a productive iron ore from granite, and would very possibly have passed the rock over as being utterly useless for such a purpose. Yet the Khasis discovered the mineral, and in all parts of the hills ancient heaps of slag testify to the use they made of their discovery; moreover, they obtained the ore by a process which was ingenious and even scientific—in fact, a kind of hydraulic mining somewhat similar to the latest process devised for obtaining gold in California. Can it be doubted that, if any other useful minerals existed in their hills, the Khasis would have found and worked them long ago? Similarly, in Kashmir, any mineral deposits that exist are probably well known to the natives, and, if useful, are already worked, and these are not of any great importance.

AT a recent meeting of the Wellington Philosophical Society, New Zealand, Mr. Hulke exhibited a specimen of a strange spider that carried its young on its body without web or filament, but simply attached to the body, until they were able to run by themselves.

MR. JOHN WHELDON has issued Part I. of a catalogue of botanical works, including the library of the Rev. M. J. Berkeley.

THE Glasgow and West of Scotland Technical College has issued its Calendar for the year 1890–91. The main objects of this institution are to afford a suitable education to those who wish to qualify themselves for following an industrial profession or trade, and to train teachers for technical schools.

WE have received the author's Hairless Paper-Pad Holder and Paper-Pad, issued by the Leadenhall Press. The Paper-Pad consists of a block of fifty sheets ($7\frac{1}{2} \times 8\frac{3}{4}$) of smooth and cream-tinted paper mounted together on a stout piece of blotting-paper, the price charged being only that for common scribbling-paper. The Paper-Pad holder is made of light wood, and should be grasped by the left hand, the right hand being free to travel over the surface of the paper-pad which is placed on it. After each sheet is used, it is torn off and placed under the pad and so blotted, and by this means the height of the pad and holder is kept constant. For writing in railway carriages, and for reporting, this form of support will be most serviceable, and it might also be used for the support of sketching-blocks.

MESSRS. MARLBOROUGH, GOULD, AND CO. are issuing what they call Marlborough pamphlet cases, the object of which is to preserve pamphlets from dust and destruction. The cases have no springs or other contrivances that could injure the contents by pressure, and in the bookshelf they resemble ordinary volumes, being "rounded and cloth-backed." The makers have sent us a case specially intended for numbers of NATURE.

THE additions to the Zoological Society's Gardens during the past week include two Brown Bears (*Ursus arctos* ♂ ♀) from Russia, presented respectively by Mr. A. C. de Lafontaine and Mr. D. B. Gellibrand; a Panolia Deer (*Cervus eldi* ♂), a Common Goat (*Capra hircus* ♂) from British Burmah, presented by Mr. Charles C. Galbraith; a Water Pipit (*Anthus spipoletta*), European, presented by Commander W. M. Latham, R.N., F.Z.S.; ten Common Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. W. Mauger; seven Oyster-catchers (*Hæmatopus ostralegus*), European, purchased; an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on August 21 = 20h. 0m. 41s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) This is the so-called "Dumb-bell Nebula." Dr. Huggins's record of the spectrum is as follows:—"The light of this nebula, after passing through the prisms, seemed concentrated in a bright line. This line appeared nebulous at the edges. No trace of the other lines was perceived, nor was a faint continuous spectrum detected. The light from different parts of the nebula is identical in refrangibility, and varies only in degree of intensity." The line referred to is, of course, the chief nebula line, near λ 500, and it will be seen that in this case it was not perfectly sharp and well-defined. It is important that the observation should be repeated by as many impartial observers as possible, as there is still a difference of opinion as to whether the line is really sharply defined or not. Other lines may also be looked for. Prof. Winlock simply observed that the spectrum consisted of a single line, and no continuous spectrum.

(2, 3, 4) These are the three "bright-line stars" first observed by Wolf and Rayet in 1867, and called by them 1st, 2nd, and 3rd Cygnus, respectively. They were subsequently observed in greater detail by Vogel, who found that many lines were common. It has been shown that most of the lines can be explained by a reference to the low-temperature spectra of manganese, iron, and sodium, in addition to the radiation of hydrogen and carbon. The most striking feature of the spectra is undoubtedly the bright band in the blue, which, standing out beyond the continuous spectrum, gives rise to an apparent absorption band on the less refrangible side. My own observations, and those of Mr. Lockyer, have shown that this band is coincident with the blue band seen in the spectrum of the spirit-lamp flame, and is therefore probably due to carbon. This conclusion is supported by the presence of another carbon fluting, near λ 517, which, however, is not so obviously seen because of the brighter continuous spectrum in that region. These are the brightest bands seen in the spectra of comets at mean distances from the sun, and the similarity leads to the conclusion that the structure of comets and bright-line stars is identical (see NATURE, August 7, p. 344). Bright-line stars are therefore probably swarms of meteorites. It is desirable that the coincidence of the carbon bands with those of the "stars" should be confirmed by other observers.

(5) The spectrum of this star is a well-marked one of Group II., the bands 2–9 being wide and dark. It is probably one of mean condensation, and the bright carbon flutings should therefore be well seen. It will be interesting also to know what dark lines, if any, are present at this stage.

(6) A star of the solar type (Vogel). Is the temperature increasing (Group III.) or decreasing (Group V.)?

(7) A star of Group IV. Observations of the comparative intensities of the hydrogen and other lines are required, in order that the temperature relatively to other stars of the group may be determined.

(8) This is a relatively bright star of Group VI., showing the secondary bands 2, 3, 4, 5, and 8, in addition to the usual carbon bands, which are very wide and dark. As in other stars of the group, further details, especially the presence or absence of solar lines, should be looked for.

(9) This variable of Group VI. will reach a maximum about August 25, the period being about 485 days. The magnitude at maximum is 7·4–8·5, and that at minimum about 11·5. I may repeat that we as yet know nothing of the spectroscopic changes which accompany the increase of light in a star of this kind, and continuous observations will therefore be of the utmost value. It has been suggested by Mr. Lockyer that the chief variation may be the relative paling of the principal bands at maximum. Colour changes should also be noted.

A. FOWLER.

MOSCOW OBSERVATORY.—Prof. Th. Bredichin has issued the second volume of the second series of *Annales de l'Observatoire de Moscou*, and it contains some interesting papers. In one "On the Origin of Periodic Comets," Prof. Bredichin brings forward many important facts. He first points out the similarity of the elements of some comets, and adduces evidence to show that they probably once formed part of a single comet which has become disintegrated by explosions and planetary perturbations; the multiple comets of Biela, Liais (1860), and 1882 II. being quoted as examples of such a development. After deducing the expressions for eruptions which do not take place in the plane of the orbit of the generating comet, and applying them to some examples, the elements of twenty-nine comets having a period less than 100 years is given, and some considerations relative to their perihelion distances, small inclinations, and direct movement are urged, as opposed to the hypothesis of the immediate transformation of parabolic to elliptic orbits. Two tables of 290 non-periodic comets arranged in the order of their perihelion distance (q), and 44 comets which have developed comæ, will be useful, irrespective of the fact that they demonstrate that when the value of q is sensibly greater than 1 the comet has little ability to develop eruptive phenomena and to produce new comets. A division of periodic comets into four groups is made, the periodic time of the respective groups being 73·8, 33·1, 14·1, and 6·0 years, and it is shown that the values of the eruptive action increases as the period decreases. The influence of Jupiter and Saturn on cometary orbits is, of course, considered, and some relations are pointed out between the times of revolution of the above-mentioned groups and those of these two planets. In another long paper "On the Origin of Shooting Stars," Prof. Bredichin attempts to prove that all meteors are ejections from comets. A paper by M. P. Sternberg gives the results of some determiuations of the length of the seconds pendulum made by Prof. Bredichin and himself in 1888–89 in various parts of Russia and Europe; and another paper, by M. Ceraski, "On Luminous Clouds," contains some interesting facts. On June 26, 1885, from observations made at two stations, separated by 10 kilometres, the vertical height of a luminous cloud was found to be nearly 75 kilometres. A map is also given for putting down observations of the paths of Perseid meteors, and this, with the eleven papers, renders the volume for 1890 as good as its predecessors.

LEANDER MCCORMICK OBSERVATORY.—Vol. i., Part 4, of the Publications of the Leander McCormick Observatory of the University of Virginia contains some double-star observations made in 1885–86. The working list from which the double stars were selected contained all known pairs between −30° and 0° having distances less than 4″, and several very close and difficult pairs north of the equator. The observers were Messrs. F. P. Leavenworth and Frank Muller, and the measures appear to have been made with much care.

COGGIA'S AND DENNING'S COMETS (*b* AND *c* 1890).—The following ephemerides are given by Dr. Berberich in *Astronomische Nachrichten*, No. 2984:—

Ephemerides for Berlin Midnight.

The brightness at discovery has been taken as unity.

SEXUAL SELECTION IN SPIDERS.

EVERY student of zoology who, of late years, has attempted to follow the drift of all that has been written on the subject of natural selection cannot fail to have observed that the less important, though not less interesting, hypothesis of sexual selection has received relatively little attention. It must be seen, in fact, that to all intents and purposes the hypothesis has remained in the state in which it was left by Mr. Wallace's criticisms—lately repeated and extended in "Darwinism"—of Mr. Darwin's views. And further, it will probably be admitted that this circumstance is to be attributed, not to the fact that there exists amongst zoologists unanimity of opinion on the point—far from it; but to the fact that, owing to the great practical difficulties in the way of making fresh observations on the courtship of new groups of animals, there has been little or nothing to add to what has been already said. Consequently any contribution to the subject should be gladly welcomed; and no apology is needed for drawing attention to a paper on the "Sexual Selection of Spiders," which was published last year in the United States of America.

Moreover, since the paper in question is one of the occasional papers of the Natural History Society of Wisconsin, it is not likely to obtain a wide circulation, at all events on this side of the Atlantic, and to meet with that attention which all who read it must admit that it deserves. The author, Mr. G. W. Peckham, whose name has been for some years past well known to those who have devoted their time to the study of spiders, has in the present instance produced a work of much greater general interest than any that he has published before. For the series of observations which constitute a large part of its subject-matter affords a means of testing in practically an unworked order of animals—and one especially favourable for the purpose—the two hypotheses respecting sexual ornamentation formulated by Mr. Darwin and Mr. Wallace. And since the conclusions to be derived from these observations are, in the opinion of the author, all in favour of Mr. Darwin's views, it will be of interest to see from a critical examination of the contents of the paper to what extent this opinion is supported by the facts therein set forth.

Mr. Darwin's theory of sexual selection, or in other words the theory that the brilliant colours and ornaments of the male are due to the constant preference by the female of the best-decked males, is too well known to need further explanation here. Mr. Wallace, rejecting this theory on the grounds that there is but little evidence in its favour and much that is directly opposed to it, has put forward an alternative hypothesis which may be briefly epitomized as follows. The production of colour in organisms is normal, and needs no special accounting for; the more brilliant colouring of the male, the development of plumes, &c., is attributable to the greater vigour and activity of this sex, and when this colouring becomes intensified at the breeding season it is because vitality is then at a maximum; the duller colouring of the female, at all events in birds, is due, through the agency of natural selection, to the toning down or elimination of the normal tints on account of her special need for concealment.

Before proceeding to test these two theories in the light thrown upon the subject by a consideration of the secondary sexual characters of spiders, Mr. Peckham, turning his attention to other groups, urges the following cases as inexplicable by Mr. Wallace's views. If, it is asked, there is a causal relation between high vitality and ornamentation, how are we to account for the brilliant colours of some tropical pigeons which are remarkable neither for pugnacity nor activity? and how for the gaudy plumes of the birds of Paradise, which are by no means noticeable for fierceness of disposition? But in the case of these two objections the flaw seems to be the assumption that pugnacity and activity are the only criteria of high vitality.

It is clear, moreover, that at the time these were advanced the author had never read Mr. Wallace's last work, "Darwinism"; for on p. 292 of this volume reference is made to the birds of Paradise, and their gaudy adornment is spoken of in connection with the wonderful activity they display. The following question is also raised. Quoting *verbatim*—"Perhaps the most difficult fact to reconcile with the [Mr. Wallace's] theory is the absence of ornamentation and bright colour in the bats. They have a wide expanse of integument, and great activity, the conditions specified by Mr. Wallace for the development of gaudy pigment, and nothing, apparently, in their habits to keep it down; but, except in the frugivorous bats, we find little difference between the sexes, nor is there any appreciable approach to bright colours" (p. 9).

At first sight this objection seems to be valid; for, if we admit the truth of the author's premises, it seems that his conclusion is a just one. But can this be done? Is it the case that there is nothing in the habits of bats to keep down the development of gaudy pigment? Surely not. These animals are nocturnal or crepuscular, spending the day suspended from the roof of some cave or other dark secluded spot, and only issuing forth at nightfall to exercise their activity in hunting for prey. Thus that great expanse of integument above referred to—namely, the wings—is never exposed to the rays of the sun, and few things, if any, are more antagonistic to the development of gaudy pigment than absence of light.

These cases, then, do not seem upon examination to be seriously opposed to Mr. Wallace's views. But turning to the spiders, we find that the objections are of a somewhat different order from those hitherto considered. For after passing in review all the principal families of this group, and studying their moults, it is concluded (1) that there is no evidence to show that there is a causal relation between high vitality and adornment, since, in the first place, as a rule, the savage and powerful female is less, sometimes very much less, brightly coloured than the male, who is comparatively weak and unaggressive; and, in the second place, many of the sluggish and sedentary spiders, such as, *e.g.*, the *Epeiridæ*, are brilliantly tinted, whilst other active, restless forms, such as most *Lycosidæ*, are relatively dull-coloured; (2) that when the male differs from the female he departs in proportion from the normal colouring of the group, and that when the female, as well as the male, is showily attired, the resemblance between them is due to the partial or complete transmission of the male colouring to the female, the completeness of the resemblance depending upon the age of the male at the time of the acquisition of his adornments; and (3) that there is no reason to think that the females have had their colours toned down for the sake of concealment at the time of nesting, for in the *Attidæ*, where sexual differences of colour are best marked, the females have covered nests.

Mr. Wallace's theory, then, however satisfactory it may be in the case of butterflies and birds, fails apparently in every essential respect when applied to spiders. It is necessary, therefore, to look elsewhere for an explanation.

Now, when we consider the secondary sexual characters of the *Attidæ*, the first fact that strikes the attention is that these characters exist in the males as modifications in the form of the falces, palpi, first pair of legs, or clypeus—that is, of those portions of the anterior part of the body which are in full view when the male is approaching the female—and, moreover, that these modifications in form result often in an increase of surface for the development of gaudy, often strongly iridescent, hues.

Thus, in *Salticus formicarius* the ♀ has short vertical reddish-black falces, while those of the ♂ are horizontal, much enlarged, and copper-green in colour; and in *Icius palmarum* "the falces in the ♂ are compressed, horizontal, and three times as long as the face, the fang equalling the falx in length; the front surface of the falces is dark bronzy rufus, and on each outer edge is a wide band of snowy-white hairs. In the ♀ the falces are vertical, and only as long as the face, and the snowy-white hairs are absent. The ♂ is rendered still more striking by the long snowy-white hairs which cover his clypeus, while the forehead, and a space just below the first row of eyes, is covered with bright red hairs. All this ornamentation is lacking in the ♀."

The clypeus, too, is liable to a considerable amount of variation with sex. Thus, in *Dendryphantes capitatus* this part in the ♂ is conspicuously marked by several white bands, which contrast strikingly with the dark colour of the rest of the face; in the ♀ the whole clypeus is whitish, and in no way conspicuous. Again, in *Mopsus mormon* there is a high vertical ridge of hairs extending over the forehead in the ♂; in the ♀, on the other hand, these hairs are wholly absent. So, too, in the *Theridiidæ*, the heads of the males are frequently higher, in many species very much higher, than in the females.

With regard to the palpi and first pair of legs, it will be sufficient to say that in Keyserling's "Arachniden Australiens" thirty-four males are described (in the family *Attidæ*), having well-developed fringes or tufts of hair on the palpi, while there are only five females so ornamented, and several of these to only a moderate extent; and that in the ♂ of *Synageles picata* the tibia of the first pair of legs is enlarged and flattened, and the anterior face of the enlargement is of a brilliant steel-blue colour; in the ♂ of *Philæus metallescens* the anterior legs are elongate, of a brilliant steel-blue colour, and ornamented with rings, spots, and fringes of hairs, whilst in the females of these

two species the legs are neither modified nor adorned to any remarkable extent.

It must be understood that the few instances here given of the secondary sexual characters have been selected out of a number cited by the author, who could himself have filled a volume on the subject. Sufficient, however, have been given to show how commonly the anterior portion of the body varies in different ways in the male sex; and "it is of high importance to note that the bright-coloured hairs or metallic scales as well as the protuberances are either on the anterior surface, or in some way so placed as to be plainly in view from the front."

In seeking for an explanation of these sexual characters it does not appear that any of them are of special advantage to their possessors in the way of procuring food, avoiding enemies, fighting with rivals, &c.; consequently they cannot be attributed to the action of natural selection. But when considered in connection with the habits of the *Attidæ* at the time of mating, it is clear to the mind of the author that the clue is to be found in the theory of sexual selection. The courtship of a number of captive species is described, and described with a sense of the ludicrous which is quite irresistible. The following two may be selected as instances.

On p. 37 we read of *Saitis pulex*:—"On May 24, we found a mature female, and placed her in one of the larger boxes, and the next day we put a male in with her. He saw her as she stood perfectly still, twelve inches away; the glance seemed to excite him, and he at once moved towards her; when some four inches from her he stood still, and then began the most remarkable performances that an amorous male could offer to an admiring female. She eyed him eagerly, changing her position from time to time so that he might be always in view. He, raising his whole body on one side by straightening out the legs, and lowering it on the other by folding the first two pairs of legs up and under, leaned so far over as to be in danger of losing his balance, which he only maintained by sidling rapidly towards the lowered side. The palpus, too, on this side was turned back to correspond to the direction of the legs nearest it. He moved in a semicircle for about two inches, and then instantly reversed the position of the legs and circled in the opposite direction, gradually approaching nearer and nearer to the female. Now she dashes towards him, while he, raising his first pair of legs, extends them upward and forward as if to hold her off, but withal slowly retreats. Again and again he circles from side to side, she gazing towards him in a softer mood, evidently admiring the grace of his antics. This is repeated until we have counted 111 circles made by the ardent little male. Now he approaches nearer and nearer, and when almost within reach whirls madly around and around her, she joining and whirling with him in a giddy maze. Again he falls back and resumes his semicircular motions, with his body tilted over; she, all excitement, lowers her head and raises her body so that it is almost vertical; both draw nearer; she moves slowly under him, he crawling over her head, and the mating is accomplished."

Again, on p. 47, concerning *Dendryphantes elegans*:—"While from three to five inches distant from her, he begins to wave his plumy first legs in a way that reminds one of a windmill. She eyes him fiercely, and, he keeps at a proper distance for a long time. If he comes close she dashes at him, and he quickly retreats. Sometimes he becomes bolder, and when within an inch, pauses, with the first legs outstretched before him, not raised as is common in other species; the palpi also are held stiffly out in front with the points together. Again she drives him off, and so the play continues. Now the male grows excited as he approaches her, and while still several inches away, whirls completely around and around; pausing, he runs closer and begins to make his abdomen quiver as he stands on tip-toe in front of her. Prancing from side to side, he grows bolder and bolder, while she seems less fierce, and yielding to the excitement, lifts up her magnificently iridescent abdomen, holding it at one time vertical, and at another sideways to him. She no longer rushes at him, but retreats a little as he approaches. At last he comes close to her, lying flat, with his first legs stretched out and quivering. With the tips of his front legs he gently pats her; this seems to arouse the old demon of resistance, and she drives him back. Again and again he pats her with a caressing movement, gradually creeping nearer and nearer, which she now permits without resistance, until he crawls over her head to her abdomen, far enough to reach the epigynum with his palpus."

From these cases and the others that are given it is established that the attitudes and antics of the males are such as to display to the best advantage whatever adornments they possess, and it is concluded that the female selects as her mate the male which pleases her best on account of some superiority over his fellows in adornment either of colour, or special outgrowths, or both. Hence is deduced the further conclusion that the sexual ornaments of the male result from the constant preference by the females of the best-decorated males. But it is obvious that this conclusion is open to the same criticism as that advanced against Mr. Darwin's explanation of the sexual ornamentation of, *e.g.*, birds—namely, the criticism that the conclusion rests upon an inference and not upon a fact; and that the most important link in the whole chain of evidence is wanting—namely, the proof that the females select as partners the most beautiful males. This it will be remembered, is perhaps Mr. Wallace's strongest objection to the hypothesis of sexual selection; and when we consider all the cases that are quoted in this work it will be seen that many of those that are advanced as supporting this hypothesis are equally explicable by Mr. Wallace's views. Thus, although it is certainly the case that the females are as a rule the more powerful and more ferocious, yet, on the other hand, judging from the descriptions given of the contests and dances of the males, it seems to be this sex which excels in activity; and if activity be a criterion of high vitality we at once see the connection between high vitality and ornamentation. Again, from the fact that the female watches with attention the antics and gambols of the male, it is inferred that she is admiring the display of his agility and beauty: that, of course, may be the case, but is it not conceivable, considering the ferocity of her disposition, that she is merely on the alert to ward off an unwelcome advance, or is but awaiting a favourable opportunity to seize and destroy her persecutor? Or again, if it be asked why it is that the males perform the strange antics in the presence of the females if it be not for display, it may be answered that the excitement of the males, always great during the breeding season, attains to a maximum at that time in the society of the females, and shows itself in the performance of the strange antics that are so graphically described. The same objection may be made to the idea expressed on p. 41 that the seemingly terrible battles of the males are all sham affairs gotten up for the purpose of displaying before the females. The fact that the males fight when there is no female to watch them makes it more probable that the combats are due to playful excitability or genuine ferocity. And lastly, not only, as above stated, is there a lack of evidence to show that the female prefers as partner the most beautiful male; but, more than that, it appears that the success of one male over another in courtship may be attributed to excess of vigour. Thus, in the case of *Astia vittata*, a species in which there are two types of male, it is stated on p. 54 that "the *niger* form is much the more lively of the two, and whenever the two varieties were seen to compete for a female, the black one was successful. He is bolder in his manners . . ."[1]

Thus Mr. Peckham has not yet brought forward a sufficient number of facts to carry to all minds that conviction of the truth of the theory of sexual selection which he feels himself. But whatever be the value of the criticisms here advanced, and of others that will doubtless be thought of, everyone will admit that the paper contributes a number of new and interesting facts to the subject of sexual adornment, and most of its readers will probably feel inclined to think that the balance of the evidence, so far as spiders are concerned, tends to support the explanation proposed by Mr. Darwin.

R. I. POCOCK.

THE TERMINOLOGY OF HYDROLYSIS, ESPECIALLY AS EFFECTED BY "FERMENTS."

ALL who consider the meaning of words, and who desire, as far as possible, to remove ambiguity from the terms employed in denoting chemical change, must have felt some dissatisfaction with the nomenclature used, chiefly by physiologists, in describing and discussing the remarkable phenomena

[1] In connection with this passage it is necessary to explain that at the time it was written I was not aware that Mr. Poulton, in his new work on "The Colours of Animals," cites the case of *Astia vittata* as affording the strongest support to the theory of sexual selection; nor did I see Mr. Wallace's review of this work in NATURE of July 24 (p. 289) until after the present article had been sent to the publisher. Consequently I had no means of knowing what Mr. Wallace's opinion on the point might be—except in so far as his reply to Mr. Poulton is the only one that common sense would immediately suggest to any man who holds Mr. Wallace's views on sexual ornamentation, or who criticizes the subject without prejudging it.—R. I. P.

presented by the living cell and which attend digestion. As Messrs. Brown and Morris in their paper "On the Germination of the Gramineæ" (Chem. Soc. Trans. 1890, 458) have done me the honour to accept several of my suggestions, I venture to regard the opportunity as one which should not be lost of discussing the terminology of fermentation phenomena.

Changes such as a glucose undergoes when it is resolved into carbon dioxide and ethyl alcohol take place under the influence of the living organism, and there is every reason to believe only *within* the cell: they involve the formation of products containing in the gross neither more nor less than the original elements of the compound fermented; and when the products are compared with the compound from which they are derived, it is seen that their production in all cases involves the separation of carbon atoms which were directly united, and also considerable rearrangement of the constituent elements.

Changes such as that which cane-sugar undergoes on inversion take place not only within the cell but equally well without it under the influence of a substance which, although not living, is of vital origin: they appear always to involve the fixation of the elements of water; and the products of their action bear a very simple relation to the original substance, viz. always that of an alcohol to its ether, no separation of directly-united carbon-atoms, or any molecular rearrangement such as attends the former class of actions, taking place. The agents derived from organisms which effect changes of this second kind are spoken of as *unorganized ferments;* changes of the first kind are said to be conditioned by *organized ferments, i.e. organisms.*

There is thus, at the outset, a difficulty in assigning a consistent meaning to either term—fermentation or ferment; diverse phenomena produced by diverse agents being included under a single designation.

Fermentation.—The difficulty is in part met by restricting the term fermentation to changes such as occur, for example, during alcoholic fermentation; and there would seem to be no occasion to apply it more widely so as to include changes of the second kind, these, as before remarked, being apparently all cases of *simple hydrolysis.* This is true, even if the explanation of fermentation suggested by Baeyer in 1870 (cf. *Ber.*, 1870, 63; Journal of the Chemical Society, 1871, 331) be accepted, which represents fermentation proper as the outcome of hydrolysis—an explanation which the increase of knowledge in the interval entirely favours; inasmuch as hydrolysis takes place in the two cases with different results, and affects compounds of different types. Moreover, it is to be noted that not only is it impossible to represent the phenomena of fermentation proper as the outcome of simple hydrolysis, but that also, in certain cases, synthetic as well as analytic changes occur; in the case of butyric fermentation, for example. In fact, in many instances, apparently two series of concurrent changes take place: the one series involving what, in the light of Baeyer's explanation, may be termed *recurrent* as distinguished from *simple* hydrolysis; the other involving the interaction of the molecules of one or more products of this recurrent hydrolysis. There is thus an advantage in employing a somewhat empirical expression in connoting phenomena which do not all conform to one absolute type, but which have a common origin, as they are the outcome of protoplasmic activity, especially as most fermentations are attended with evolution of gas.

But it is to be remembered that, whereas carbohydrates and allied compounds such as glycerol, lactic acid, &c., are said to undergo *fermentation*, the decomposition of albuminoids under the influence of organisms is commonly termed *putrefaction;* this distinction, however, is made on account of the character of the products, not because there is any reason to suppose that the changes which occur are essentially different in character from those which the carbohydrates undergo. The want of a term indicative of the fact that the action is one which takes place under vital influence without reference to the character of the change—equally applicable to simplifications such as occur during alcoholic fermentation and to complications such as occur during butyric fermentation—is also felt in the case of changes such as alcohol undergoes under the influence of *Mycoderma aceti* and *vini*, or which ammonia undergoes on nitrification, and in the converse change of denitrification. Dr. W. Roberts has proposed to speak of changes induced by enzymes (*v. infra*) as cases of *enzymosis;* the corresponding term *zymosis* might well be employed as the synonym of fermentation, and would probably be found to be of more general application: thus alcohol may be said to undergo oxidation by zymosis or zymic oxidation under the influence of *Mycoderma aceti;* and in discussing putrefactive changes, it would be possible to speak of zymic changes as distinct from those arising from the unassisted interaction of the zymic products. Zymosis is preferable to *zymolysis*, as the effect is not always one of simplification.

Ferments.—The expression *ferment* is more frequently than not employed as the equivalent of *unorganized ferment;* consequently it is applied to the very agents which are incapable of producing fermentation proper. This has been so generally felt to be the case that several words have been coined in place of unorganized ferment, notably *zymase* and *enzyme* (cf. Dr. W. Roberts, Roy. Soc. Proc., 1881, xxxi. 145): the objection may be made to the former that it is indicative of vitality; the latter, however, is expressive, and serves only to indicate the vital origin of the agent, thus differentiating it from agents such as the mineral acids which act very similarly.

Enzymic action or enzymosis[1]—to use the phrase suggested by Dr. Roberts—appears, as already remarked, always to involve decomposition by means of water. On this account, in 1880, in the second edition of my "Introduction to the Study of Organic Chemistry" (Longmans; footnote, p. 190) I put forward the following suggestions:—

"Decompositions like those of starch into dextrose, of cane-sugar into dextrose and lævulose, of the fats into glycerine and an acid, or of ordinary ether into ethylic alcohol, which involve the fixation of the elements of water, may all be said to be the result of *hydrolysis;* and those substances which, like sulphuric acid, diastase, emulsin, &c., induce hydrolysis may be termed hydrolytic agents or *hydrolysts.* The substance hydrolyzed is the *hydrolyte.* The mere fixation of the elements of water, unaccompanied by decomposition, as in the conversion of ethylenic oxide into glycol, $C_2H_4O + OH_2 = C_2H_4(OH)_2$, may be termed hydration in contradistinction."

It is usually necessary to employ a specific enzyme (hydrolyst), or one of a very limited number, to effect the hydrolysis of any particular hydrolyte, and hence physiologists are in the habit of speaking of *amylolytic* ferments, *proteolytic* ferments, &c., meaning ferments capable of *splitting up* starch, proteids, &c. But the terms amylolytic, proteolytic, &c., are confusing to the student who has learnt that electrolysis signifies splitting up *by means of* electricity, and hydrolysis splitting up *by means of* water—not the splitting up *of* electricity or *of* water. As electrolysis and even hydrolysis are well-established terms which it would scarcely be politic to alter, it appears highly desirable to abandon the use of terms such as amylolytic, proteolytic, &c., and I would suggest that an enzyme capable of inducing the hydrolysis of starch should be termed an *amylo-hydrolyst;* one which affects albuminoids, a *proteid-hydrolyst;* one which affects fats, a *glyceride-hydrolyst.*

One case remains in which the use of the term ferment cannot be avoided by the adoption of this proposition—that of the so-called rennet ferment. It may well be that this is also a hydrolyst, and that in all cases the formation of a curd, clot, or coagulum initially involves hydrolysis—or, perhaps, hydration merely—and the consequent interaction of molecules of the product or products; but of this we know nothing at present, and the observed phenomena are of so different a character that it is desirable to connote such changes by a distinct expression. I would suggest that we should term the rennets *thrombogenic enzymes* or *thrombogens.*

HENRY E. ARMSTRONG.

[1] Sheridan Lea's zymolysis (cf. *Journal of Physiology*, 1890, xi. 254) is open to the objection above made to zymase.

SCIENTIFIC SERIALS.

L'Anthropologie, sous la direction de MM. Cartailhac, Hamy, et Topinard, tome i., No. 2 (Paris, 1890).—The covered mortuary-chambers at Les Mureaux (Seine-et-Oise), by Dr. Verneau. Through the accidental displacement of the soil in a field at Les Mureaux an important discovery was made in the winter of 1888–89 of a subterranean sepulchral passage, a so-called *allée couverte*, which was densely packed with human bones, intermingled with various stone, bone, and other objects. As in other constructions of the kind, this mortuary passage was divided into two paved and walled-in chambers, varying in width from 1·85 m. to 2·10 m. Owing to the thickness of the stone walls dividing these chambers, considerable labour must have been required to effect an entrance whenever a fresh burial took place. It would appear that sixty or more skeletons had been deposited in these chambers, but unfortunately many

of the bones were damaged or utterly destroyed by the workmen originally engaged in the excavations. In the course of M. Verneau's examination of these sepulchral chambers, he discovered that a special burying-place had been allotted to children close to the stone hearth, which was placed at the entrance of the *allée*, while the adult skeletons had been deposited in other parts of the chambers. He is of opinion that the *foyer* or hearth was designed to facilitate the ventilation of the air before the chamber was opened for the deposition of fresh bodies, but the presence in the surrounding ashes of half-burnt animal bones suggests the possibility that these rudely constructed hearths may have been used for the preparation of funeral repasts. The great number of artificially perforated cranial bones proves that the process of trepanning was of frequent occurrence amongst the Neolithic tribes of Les Mureaux. The great variety of cranial types, which range from the extremes of brachycephalism to those of dolichocephalism, shows that a blending of several distinct races had taken place prior to the settlement of these early people. The objects found at Les Mureaux, moreover, indicate that these tribes must have had communication with distant regions, for while the stones of which the *allée* is built have been obtained from the opposite shores of the River Seine, some of the shells, as patella, purpura, and others used for ornamentation, must have been derived from intercourse with people of the remote sea-coast. Perforated flint and bone pendants were found on several of the skeletons, as many as five of these objects being suspended around the neck of a very young child.—On the dietary of the Lapps, by M. Rabot. The author has borrowed so largely from the narratives of earlier foreign travellers, and more especially from those of Dr. Broch and other Danish writers, that his work can lay no claim to originality. According to the author it would seem that we are justified in assuming that the sedentary Lapps and most of those who have entirely given up a nomadic life live almost exclusively on fish, while the pastoral section of the people prefer animal food.—The cephalic index in the population of France, by Dr. Collignon. The author here shows how we may trace in the distribution of various cephalic indices the main centres of the different races which have occupied the French territories. Among the various peoples settled in France he distinguishes three groups—namely, (1) a Ligurian or Iberian people, the representatives of the Cro Magnon and other primitive tribes, who exhibited the dolichocephalic type, with a short stature and a brunette coloration. This race appears to have spread from the Gulf of Lyons to the Maritime Alps. (2) A Celtic brachycephalic race, which predominated in the districts extending from the Mediterranan to the eastern limits of France. (3) A blonde dolichocephalic people, who had forced themselves wedge-like through the Celtic mass of the population, separating it into two sections, and advancing from north-east to south-west.

THEORETICAL BALLISTICS.

A Revised Account of the Experiments made with the Bashforth Chronograph, to find the Resistance of the Air to the Motion of Projectiles, &c. By Francis Bashforth, B.D., late Professor of Applied Mathematics to the Advanced Class of R.A. Officers, Woolwich, and formerly Fellow of St. John's College, Cambridge. (Cambridge: University Press, 1890.)

ROBINS, in the last century, revolutionized the science of artillery by his invention of the ballistic pendulum; and in our own times Mr. Bashforth has accomplished the same thing for modern rifled artillery, by the aid of electricity and by his own chronograph.

Previous to Robins's experiments, the vaguest ideas prevailed as to the velocity of cannon shot and musket bullets: it was never supposed that such a light medium as the air could offer the enormous resistance it does and the resistance of the air being supposed almost insensible, and Galileo's parabolic theory being applied, the velocity of projectiles was very much underestimated. At the same time, to reconcile Galileo's theory with the observed ranges in practice, it was usual to suppose the first part of the trajectory to be a finite straight line, the *point-blank range*, and to add the parabola at the end of the straight line.

The ballistic pendulum of Robins enables us to dilute the velocity of the bullet so as to make it easily measurable; and by firing at the pendulum from different distances, and calculating the loss of velocity through the air, we are able to obtain a fair estimate of the resistance. Robins found in this manner that the resistance of the air to a bullet, three-quarters of an inch in diameter, weighing one-twelfth of a pound, is about 10 pounds, or 120 times the weight of the bullet at a velocity of about 1600 feet per second. By firing with a charge of powder half the weight of the ball at the ballistic pendulum at ranges of 25, 75, and 125 feet, he found that the mean velocities of impact were respectively 1670, 1550, and 1425 f.s.

Now denoting by R the average resistance in pounds over the first 50 feet, in which the velocity fell from 1670 to 1550, the principle of energy gives, in foot-pounds,

$$50R = \frac{1670^2 - 1550^2}{2 \times 32 \cdot 2 \times 12}, \text{ or } R = 10.$$

Robins proceeds to theorize by the principle of mechanical similitude, and shows that a 24-pound cannon-ball fired with a charge of 16 pounds of powder, should acquire a velocity of 1650 f.s., and that the resistance of the air would then amount to 540 pounds, or nearly twenty-three times the weight of the shot. He is now able to clear up the difficulty of the supposed point-blank range, the distance during which the shot is conceived to fly in a straight line. To reconcile the parabolic theory of Galileo with the observed very small curvature of the trajectory at the outset, ancient writers on ballistics were in the habit of making a concession to the vulgar opinion (an opinion not yet extinct, although Tartaglia pointed out its fallacy) that the path of a shot was a straight line for a certain distance, called the point-blank range, during which the shot "flyeth violently," the *motus violentus* of old writers.

But now Robins is able to show that, in consequence of the much higher velocity of the shot, and the much greater resistance of the air than was ever considered, a 24-pound shot fired with two-thirds of its weight of powder, will, at a distance of 500 yards from the piece, be separated from the line of its original direction by an angle of little more than half a degree, so small an aberration as not to be noticeable with crude artillery appliances; and generally that the track of the shot departs greatly from the parabola, and is much more closely imitated by the combination of *motus violentus* in a straight line, *motus mixtus* in a curve or circular arc, and *motus naturalis* in a vertical line, the vertical asymptote of the true path, as taught by the old writers on artillery.

The treatise of Robins, "New Principles of Gunnery," 1742, attracted immediate attention, and was translated with a commentary by Euler.

The ballistic pendulum employed by Robins weighed about 56 pounds, and was used only with musket bullets; and to this day it will probably be found the most efficient instrument for measuring the velocity and retardation of small-arm projectiles; the threads or wires of the electric screens being easily missed by bullets, or, if struck, being apt to deflect them.

Experiments were made at Woolwich by Hutton in 1775 and by Gregory in 1815, and by Piobert, at Metz, in 1839, to apply the ballistic pendulum to cannon-balls; and although not such an accurate instrument on a large scale, in consequence of elasticity and vibration, still it was the only means at hand till the invention of the electric telegraph. The application of electricity to the measurement of the time of flight of the cannon-ball immediately suggested itself to various minds—Wheatstone, Konstantinoff, and Bréguet—and a chronograph was soon produced, capable of registering two instants of time, and thence one velocity; as performed at present by the Boulengé chronograph, now in universal use for the determination of muzzle velocities and the proof of powder.

Notwithstanding the obvious advantages of electricity so late as 1855 a monster ballistic pendulum was constructed to the order of the Government, and first set up at Shoeburyness, then at Woolwich, and finally dismantled without ever having been used in any course of experiments. The model alone of this instrument, shown at the Exhibition of 1862, is reported to have cost £800; but for all practical purposes the pendulum could have been replaced by a large box rammed with sand, and suspended by chains about 6 or 8 feet long, and the indications would probably have been more accurate. The experimenters who followed Robins would have succeeded better if they had expended all their care and ingenuity upon experiments on a small scale; and really with all their trouble it is found that, when checked by electric records, their results are not so accurate as the original observations carried out by Robins.

The problem of the electric chronograph was occupying Mr. Bashforth's mind when he received the appointment of Professor of Mathematics to the newly instituted Advanced Class of Artillery Officers in 1864; where he was well placed for carrying out his experimental ideas, with the assistance of his enthusiastic pupils.

The conditions to be secured which Mr. Bashforth set before himself were—

(1) The time to be measured by a clock going uniformly.

(2) The instrument to be capable of measuring the times occupied by a cannon-ball in passing over at least nine successive equal spaces.

(3) The instrument to be capable of measuring the longest known time of flight of a shot or shell.

(4) Every beat of the clock to be recorded by the interruption of the same galvanic current, and under precisely the same conditions.

(5) The time of passing each screen to be recorded by the momentary interruption of a second galvanic current, and under precisely the same conditions.

(6) Provision to be made for keeping the strings or wires of the screens in a uniform state of tension, notwithstanding the force of the wind and the blast accompanying the ball.

To secure these conditions practically, Mr. Bashforth had to invent his own chronograph, for a detailed description of which the reader must refer to the book; but it consists essentially of a brass cylinder provided with a heavy fly-wheel movable about a vertical axis; and of two markers tracing spiral lines on paper placed on the cylinder, and giving an indication by a jerk on the spiral corresponding to the cutting of one of the electric screens by the shot, or to half-seconds of the clock.

The fly-wheel being spun by hand, and the clock making continual half-second records, the word is given to fire the gun, and then the screen records are registered on the paper by the screen-marker. When the paper is full, after five or six rounds, the cylinder is transferred to a micrometer instrument, and the records read off with a vernier and microscope as accurately as possible.

We may take it that the average travel of the paper on the cylinder is an inch for about a tenth of a second, so that, with screens 150 feet apart, an average velocity of 1500 f.s. would give screen records at intervals of about an inch. Readings of tenths of an inch will give hundredths of a second, and of hundredths of an inch will give thousandths of a second, which is about as far as can be seen or measured with this instrument. But, by treating the last significant figure as indeterminate, and smoothing down irregularities by differencing and interpolation, Mr. Bashforth is able to assign probable values to the 4th and even 5th decimal of the second, in the instant at which any screen is cut.

Any improved instrument which would give a velocity to the paper of ten times or one hundred times of Mr. Bashforth's velocity would increase the recording accuracy theoretically to the same extent; but, as Mr. Bashforth claims for his instrument, he has located the shot at any instant to within about one foot of range, an error comparable with inaccuracies in the measured distance between the screens, inclination of the screens, and bending or stretching of the screen wires before breaking.

The chronograph having given us the instants of time, say $t_1, t_2, t_3, \ldots$ at which screens 1, 2, 3,... at equal intervals of l feet were cut by a shot, we have to employ the methods of Finite Differences for converting these records into expressions for the velocity and retardation at any point.

It will be noticed that the chronograph records give, by interpolation, t as a function of s, not s as a function of t, so that the velocity v is the reciprocal of dt/ds, while the retardation is $\frac{d^2t}{ds^2}v^3$; and if the shot weighs W pounds, the resistance of the air is $W\frac{d^2t}{ds^2}v^3$ poundals, or $W\frac{d^2t}{ds^2}v^3 \div g$ pounds: the shot flying so fast that, practically, we may take it as moving in a horizontal line.

Formulas of the calculus of Finite Differences will give us the values of dt/ds and d^2t/ds^2 in terms of the successive differences $\Delta t, \Delta^2 t, \ldots$ of t; those employed by Mr. Bashforth being—

$$l\frac{dt}{ds} = \Delta t - \tfrac{1}{2}\Delta^2 t + \tfrac{1}{3}\Delta^3 t \ldots\ldots$$

$$l^2\frac{d^2t}{ds^2} = \Delta^2 t - \Delta^3 t + \tfrac{11}{12}\Delta^4 t \ldots\ldots$$

To take a simple numerical illustration, suppose it was found by the chronograph that a shot weighing 70 pounds, flying horizontally, cut three equidistant screens 150 feet apart at instants of time 2·3439, 2·4325, 2·5221 seconds. The time from the first to the third screen being 0·1782 second, the average velocity over this 300 feet is $300 \div 0{\cdot}1782 = 1684$ f.s.; and we may take this as being the velocity at the middle screen—an assumption which is accurately true if the resistance varies as the cube of the velocity—that is, if d^2t/ds^2 is constant.

Again, $\Delta^2 t = 2{\cdot}3439 - 2 \times 2{\cdot}4325 + 2{\cdot}5221 = 0{\cdot}001$; so that $d^2t/ds^2 = 0{\cdot}001 \div (150)^2$; and therefore the resistance of the air is $70 \times (1684)^3 \times 0{\cdot}001 \div (150)^2 = 14{,}850$ poundals, or 464 pounds.

Experiment confirmed the reasonable hypothesis that the resistance of the air is proportional to the cross-section, or to d^2, if d is the diameter in inches; so that, for similar projectiles, Bashforth introduces his coefficient K, defined so as to make the resistance of the air at a velocity v f.s. to a projectile d inches in diameter to be—

$$d^2 K\left(\frac{v}{1000}\right)^3 \text{ poundals, or } d^2\frac{K}{g}\left(\frac{v}{1000}\right)^3 \text{ pounds};$$

while, if the weight of the shot is W pounds, the retardation due to the resistance is

$$\frac{d^2}{W}K\left(\frac{v}{1000}\right)^3 \text{ celoes};$$

and thus

$$\frac{d^2}{W}K = 10^9\frac{d^2t}{ds^2}, \text{ or } K = \frac{W}{d^2}10^9\frac{d^2t}{ds^2}.$$

The coefficient K is now found experimentally to be the same for all similar projectiles, whatever the weight, W pounds, or diameter, d inches; and the factor of mechanical similitude W/d^2, now called the ballistic coefficient and generally denoted by C, enables us to generalize the experiments made on one scale to projectiles of all sizes.

We now see the convenience of splitting up the resistance of the air into two factors, one of them being the cube of the velocity; for in the retardation the other factor is d^2t/ds^2, which is given very simply in terms of $\Delta^2 t, \ldots$

It is very often asserted that "Bashforth assumed the resistance of the air to vary as the cube of the velocity"; whereas in reality Bashforth found it convenient to take out the cube of the velocity as one factor of the resist-

ance, and to tabulate the other factor, as a slowly varying quantity.

Practically, we find that $\Delta^2 t$ is about one-thousandth of a second when $l = 150$, the distance between the screens in feet, so that d^2t/ds^2 is a decimal beginning with six or seven zeros. Mr. Bashforth avoids this inconvenience by writing the retardation—

$$10^9 \frac{d^2t}{ds^2}\left(\frac{v}{1000}\right)^3,$$

equivalent to reckoning the velocity in thousands of feet per second.

We have explained this notation at some length, as Mr. Bashforth has taken this and all other notation for granted as known, which is already given in his "Motion of Projectiles." The numerical values of K from the experiments are given in Table XI. for spherical and in Table XII. for ogival-headed projectiles; these two tables containing the complete theoretical deduction of all the author's numerous experiments.

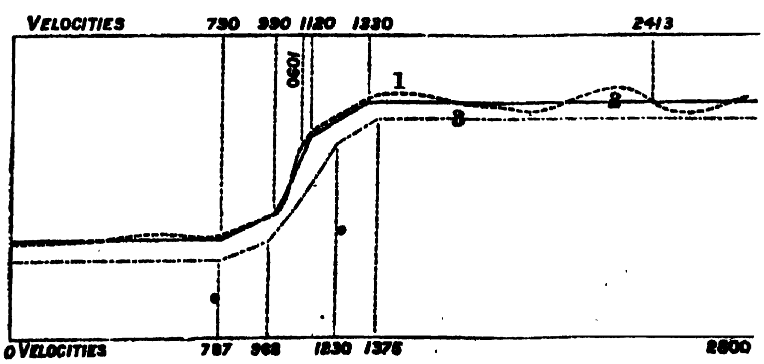
But as for very high or very low velocities the Newtonian law of resistance, varying as the square of the velocity, is more likely to be near the truth, the author has converted his coefficients K for the cubic law into coefficients k for the Newtonian quadratic law, tabulated in Tables I.–VI.; here, again, he has omitted to explain the formula required in the use of k; but it is easily inferred to mean that the resistance of the air is

$$d^2k\left(\frac{v}{1000}\right)^2 \text{ poundals, or } d^2\frac{k}{g}\left(\frac{v}{1000}\right)^2 \text{ pounds,}$$

so that the relation connecting k and K is $1000k = v\text{K}$.

In the practical use of the tables, we choose the one in which k or K is the more nearly constant and changes the slower.

The value of k for ogival-headed projectiles has been plotted graphically in the following diagram by Mr. A. G. Hadcock, quoted by Mr. Bashforth on p. 149; curve 1 being drawn from the result of Mr. Bashforth's experiments; curve 2 from the empirical laws of General Mayevski deduced from Bashforth's experiments; and curve 3 from the empirical laws of Captain Ingalls, drawn up to represent the resistance of the air according to Krupp.



The diagram is interesting as showing how far the Newtonian law is true for very low and very high velocities, and it confirms in a remarkable way the change in the value of k as we pass through the velocity of sound, so that its final value is about three times its initial value, as found out by Robins; insomuch that the resistance of the air to a 12-pound shot moving at 1700 f.s., which, according to the experiments of Newton on slow motions ("Principia," lib. ii., Props. 38–40), ought to have been 144 pounds, was found by Robins to be 433 pounds, or three times as much.

At velocities less than that of sound the projectile is always moving among its own waves; at greater velocities the point is supposed to be cleaving undisturbed air, like a swift steamer on the water; and now the chief element of resistance arises in the energy drawn off in the waves in the wake, waves which have been photographed by Mach and Salcher, according to an article signed "B." in NATURE.

Recently it has been discovered that with high velocities the shot carries the sound of the gun along with it, while backwards and sideways the sound is propagated at its ordinary rate; this phenomenon is sufficient to destroy the utility of range-finders based upon the observation of the velocity of sound.

Curve 3 indicates that the resistance of the air to Krupp's projectiles is about 10 per cent. less than to ours; this may be attributed to the sharper point, better centering obtainable with breech-loading, and a slightly less standard density of air; but Mr. Bashforth points out, with some justice, that the resemblance of Krupp's curve 3 to his own is rather suspicious, considering the small number of published experiments upon which Krupp's experiments are based.

Mr. Bashforth honestly prints all the values of K derived from his experiments, values often exhibiting great discrepancies among each other, and takes their mean as the true value; whether more delicate chronographs and improved electrical manipulation will enable us to refine on Bashforth's results remains to be seen, as a correction in the first decimal place of the value of K, depends upon the millionth of a second—a refinement we are very far off from having attained. Mr. F. J. Smith has given an account of a chronograph of his own invention, and in the August *Phil. Mag.* a description of a method of eliminating the latency in electro-magnetic records in chronographs, which may prove very useful. A chronograph to read directly to one ten-thousandth of a second is now the great desideratum: when chronographs were first brought out, the millionth of a second was glibly talked about, but so far, the thousandth is very good work indeed.

The experimental part of work is concluded when the value of K is obtained; but on these experiments Mr. Bashforth is able to build up his tables of T and S (XXIII.–XXXIII.), which enable us to calculate beforehand the performance of any gun, and save thousands of pounds in gunpowder at the price of a little ink.

Knowing C, the ballistic coefficient of the gun, then the formulas

$$t = \text{C}(\text{T}_\text{V} - \text{T}_v), \quad s = \text{C}(\text{S}_\text{V} - \text{S}_v),$$

connect the distance s in feet and the time t in seconds, for any initial velocity V, and final velocity v.

An additional table, for D, invented by Mr. W. D. Niven, is not given by Mr. Bashforth, but is found of great practical use; it gives δ, the deviation in degrees in a vertical plane for a flat trajectory, by the formula—

$$\delta = \text{C}(\text{D}_\text{V} - \text{D}_v).$$

Colonel Siacci, of the Italian artillery, has converted

Niven's D into circular measure, or natural tangents, and called it I; and has added another useful function, A, the altitude function. The use of these functions is indispensable in modern ballistics; but Mr. Bashforth does not mention them, as the chief purport of his book seems to be to put on record his own share of the work; and certainly, once the experimental part is done, it is a very easy matter to sit quietly indoors and theorize upon it.

A very searching test of Mr. Bashforth's tables was proposed in 1887, when it was decided to fire the "Jubilee rounds" from the 9·2 inch at elevations of 40°–45°, to see what is the extreme range attainable with modern artillery; and calculations were invited, to be sent in before the gun was fired. Mr. Bashforth prints the result of his calculations, which assigned a range of 19,426 yards with an elevation of 40° and an initial velocity of 2360 f.s. The range attained one day when the gun was fired was over 21,000 yards, and on another day was over 20,000, the difference being attributable to wind; so that, with no allowance for wind, and the fact that the initial velocity was really about 2375 f.s., we must consider that the calculation was close enough to show the value of Bashforth's coefficients; other calculators who allowed for the better shape and steadiness of the projectile obtaining even closer agreement. The calculation is interesting as showing the great height to which the projectile rises, and the consequent necessity for a frequent change in the coefficient of resistance due to the tenuity of the atmosphere.

Prop. VII., Robins's "New Principles of Gunnery," asserts:—"Bullets in their flight are not only depressed beneath their original direction by the action of gravity, but are also frequently driven to the right or left of that direction by the action of some other force."

This well-known effect in golf is still more marked in rifled artillery, especially with high-angle fire; and now in modern ballistic tables we have columns added for M and B, two functions calculated theoretically by General Mayevski, for assigning the value of this lateral deviation or drift.

Mr. Bashforth devotes chapter vi. to a popular exposition of this phenomenon, which is still somewhat wrapped in obscurity, in spite of all that has been written about it; a list of which writings is given by Captain Ingalls in his "Hand-book of Problems in Exterior Ballistics."

The stability of the axis of the projectile imparted by the rotation has the effect of making the head of the shot point slightly to the right of the vertical plane of fire with right-handed rotation, thus causing *drift*, and also of keeping the head a little above the tangent of the trajectory, so that in its descent the shot experiences a so-called *kite-like action*, tending to increase the range. It is well, however, for theorists to be on their guard in offering an explanation, as observers are not always agreed as to what really takes place.

Mr. Bashforth expresses a fear that, after all his labours, he will have produced very little effect; but we hasten to reassure him that his work is held in the highest estimation by those who have means of making a practical judgment.

A. G. GREENHILL.

BRITISH FOSSILS.

British Fossils, and where to seek them; an Introduction to the Study of Past Life. By J. W. Williams. Pp. 96, Illustrations. (London: Swan Sonnenschein and Co., 1890.)

AT the close of the introduction to this little volume, the author informs us that his object has been to convey to the young collector of British fossils the experience and knowledge acquired by others, whereby his own toil and labour may be lightened. The purport of this is admirable, but unfortunately the author has not succeeded in carrying out his good intentions. The volume is small, and merely a compilation; so there is no excuse for the number of errors and misprints by which its pages are disfigured.

The plan of the book seems to be to give a brief notice of each main geological horizon, with a list of some of the characteristic fossils, but we very much doubt whether long strings of generic names, like those given on p. 28, for example, are calculated to afford much assistance to the young collector, as there is practically no information as to what such terms really represent. None of the illustrations are original, the frontispiece being taken from Louis Figuier's "World before the Deluge," and most of the other figures from a well-known German work. And while on the subject of illustrations we should be glad to be informed why amphibians and reptiles like *Archegosaurus*, *Capitosaurus*, and *Placodus*, should have their skulls figured (as on pp. 45, 46) in a work on British fossils, when these genera are totally unknown from British strata. Such figures, as well as those on pp. 56, 57, may lead the inexperienced "young collector," for whom the book is avowedly written, to the conclusion that he may expect to meet with entire skulls and skeletons of fossil reptiles in his geological excursions. The proper course in these cases is, it need hardly be said, to give figures of teeth and some of the bones of such creatures, with which the tyro may be expected to meet, and to show how their generic affinities can be determined. Then, again, in reproducing the old figures of the Devonian fishes given on p. 33 the author might surely have alluded to the work of Dr. Traquair and other authorities showing how very far these figures are from being a truthful representation of these ancient creatures.

Leaving the illustrations, we may turn to the text. In glancing over the pages we were greatly puzzled to know what might be the meaning of the term *dermoid* types mentioned on p. 20, the repetition of the word indicating that it can scarcely be a misprint. Omitting mention of numerous misprints, obvious enough to the specialist, but terribly misleading to the beginner, we notice on p. 29 that *Tentaculites* is given as an Annelid, although its Pteropod affinities have long been known. Much discussion has taken place as to the affinities of the Palæozoic plant known as *Sphenophyllum*, but when on p. 43 the author calmly tells us that it is probably founded on the leaves of Calamites, he gives us a piece of information as new as it is erroneous. It is somewhat amusing to find the student referred, on p. 44, to the author's book on "Land and Fresh-water Shells," as if it were the only extant treatise on the subject; but when on p. 45 we are informed that Labyrinthodonts are characterized as a

whole by the presence of "a ventral armour of oval scales," we again have to wonder at the author's sources of information. It is indeed true that many Labyrinthodonts have a ventral armour of bony scutes, but these can scarcely be described as oval, and in the typical Labyrinthodonts, to which some authorities restrict the term, such scutes are totally wanting. The essential features by which the Labyrinthodonts are characterized the author carefully refrains from mentioning. A trap is set for the unwary on pp. 51, 52—the shell mentioned on the one page as *Ammonites bucklandi* being alluded to on the next as *Arietites bucklandi*. Equally unfortunate with the author's mention of the Labyrinthodonts is his allusion on p. 59 to the Mesozoic mammals, where he repeats the exploded idea that *Stereognathus* was an Ungulate, thus carefully ignoring all the recent work relating to that peculiar group known as the Multituberculata, which appears to be allied to the Duck-mole. On the same page *Megalosaurus* is carefully separated from the Dinosaurs, to appear as a carnivorous lizard, whereas in the list on p. 62 it is placed in the former group. How totally out of date is the list on the page last-mentioned ought, moreover, to have been known to anybody acquainted with recent palæontological literature. Page 63 is noteworthy as containing at least six misprints in the spelling of scientific names; but perhaps the climax of blunders is attained on pp. 74, 75. Thus, on the former page we are gravely told that *Hyracotherium* is a hog; and if one fact has been repeated over and over again almost *ad nauseam*, it is that *Hyracotherium* is one of the early progenitors of the horse, being, in fact, identical with the American *Eohippus*, and we can hardly believe that the author wishes the student to understand that horses are descended from hogs! On p. 75 *Lingula* is carefully separated from the Brachiopods, while the well-known Crag Polyzoan *Fascicularia*—one of the commonest of Suffolk fossils—is stated to be a shell!

Finally, the glossary is an explanation of certain mineralogical and chemical terms having for the most part no sort of connection with British (or, for the matter of that, with any other) fossils. What connection can possibly exist between "astrakanite—a compound of magnesium sulphate and sodium sulphate deposited in winter time in the salt lakes near the mouth of the Volga," and the fossils of the British Islands, we are totally at a loss to imagine. A similar remark will apply to eclogite, which is said to be a rock consisting of red garnets and hornblende; although it really is one of the pyroxenes.

R. L.

OUR BOOK SHELF.

Il Teorema del Parallelogramma delle Forze dimostrato erroneo (con figure.) By Giuseppe Casazza. (Brescia: Stabilimento Tipografico Savoldi, 1890.)

IT is curious that the mathematical paradoxer should confine himself principally to the problem of "squaring the circle"—that is, to the attempt to prove that π is the root of a quadratic equation with rational coefficients, in algebraical language; while other simpler questions are at hand in which he might prove himself superior to the conclusions of ages, by solving the problems of the "duplication of the cube" and the "trisection of an angle."

Some paradoxers attain their own ends by a wrong result, for instance, in putting $\pi = \sqrt{10}$—a result easily tested by counting the revolutions of a railway carriage wheel of given diameter, in a journey of given length; others by ignoring the rules of the game, as Napoleon is reported to have played chess.

Our author must be congratulated upon having started a fresh question of controversy, which had till now been universally regarded as settled for about three hundred years.

The "parallelogram of forces" must have been known experimentally for thousands of years longer; but in the orthodox world, what is considered at the present time the best and simplest way of proving it theoretically in a strictly rigorous manner? The proof of our youth given by Duchayla is now voted cumbrous and antiquated; and only retained by veteran examiners as a searching test of logical power. Nowadays we cannot afford the time to linger over the elements, and it is customary to treat the "parallelogram of forces" as a corollary to Newton's second law of motion; but this cannot be considered perfectly satisfactory, as we are making the fundamental theorem of statics depend upon a dynamical argument.

Maxwell pointed out that, as we were concerned with a statical theorem, it was better in the proof to ignore the word "resultant," and to present a system of balancing forces at each step; and in this way he succeeded in framing a more simple rigorous statical proof, starting from the axiom that the resultant of two equal forces bisects the angle between them.

Again, by determining the conditions of equilibrium of three parallel forces, instead of as usual determining the resultant of two parallel forces, one figure will serve for all possible cases.

Practically it is the "triangle of forces" which we always work with, and not the "parallelogram," with the advantage in graphical statics of using only three lines of construction instead of five.

To return to our author, it is difficult to make out, with an imperfect knowledge of his language, whether he is writing ironically or not. His dynamical language is very loose; he uses "force" and "velocity" as convertible; and throwing his remarks into the style of Galileo's dialogues, he seeks to controvert all Galileo's conclusions. On p. 17 he provides the critic with an appropriate and characteristic quotation with which to conclude—"ho pero spesso dei momenti in cui gettando all' aria i libri che mi trovo sotto mano, esclamo: *Ma io sono un allucinato!*"

A. G. G.

L'Esprit de Nos Bêtes. Par E. Alix. (Paris: J. B. Baillière et Fils, 1890.)

Les Facultés Mentales des Animaux. Par le Dr. Foveau de Courmelles. (Paris: J. B. Baillière et Fils, 1890.)

THE writers of these two books have very much the same object in view. Their aim is to show that the mental life of animals differs only in degree, not in kind, from that of man. If anyone still thinks that animals are merely machines, or that they have no higher faculties than instinct, it would be well worth his while to consider what either Dr. Courmelles or M. Alix has to say on the subject. No impartial person could study the evidence brought together by either of the two writers, and continue to doubt that animals display intelligence in the strictest sense of the term, and that they share in varying degrees many of the emotions which are often supposed to be exclusively characteristic of the human race. Of the two works, the one by M. Alix is the more elaborate. In both books the materials are well arranged, and the authors have persistently sought to present their facts and ideas brightly and pleasantly.

Elementary Arithmetic. By C. Pendlebury, M.A., F.R.A.S., and W. S. Beard, F.R.G.S. (London: George Bell and Sons, 1890.)

IN a book on elementary arithmetic it is necessary that there should be throughout a good and well graduated series of examples. The authors of the present volume have got together a large number of examples and problems for written work, and in addition they have arranged numerous sets for use in oral teaching form, a very important feature in an elementary work of this kind. The explanatory matter is written in intelligible and simple language, and great attention has been paid to the treatment of the money rules and the more important weights and measures.

This book is intended to serve as an introduction to the one on "Arithmetic for Schools," and the examples have been arranged so that they are all different from those given in the advanced work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

British Association Procedure.

IT has been to me a matter of surprise that a letter by Prof. O. Lodge published in these columns on October 17, 1889, did not elicit other similar communications, as the views he enunciated are undoubtedly those of a not inconsiderable number of active members of the British Association. Prof. Lodge pointed out that the British Association week undoes the benefit of the previous holiday, mainly because the conditions under which the work of the Sections is carried on are prejudicial to health. This I know from considerable personal experience to be the case; and in this and previous years I have had the remark addressed to me: "Surely you are not going to *that* British Association meeting to make yourself ill again."

Prof. Lodge suggested that the Sections should sit from 10 a.m. till 1 or 1.30 p.m., and that the Sectional Committees should meet afterwards. Such an alteration would doubtless mitigate the evils inseparable from the present system, and it is to be hoped that a determined effort will be made at the ensuing meeting to promote its adoption. A recommendation somewhat to this effect was, I believe, made to the Council by at least one of the Sections at the Birmingham meeting, but nothing came of it. This is, perhaps, not surprising; indeed, it is a question whether anything ever does come of recommendations to the Council—so some say.

Machinery devised 50 odd years ago is no longer capable of satisfactorily coping with modern requirements. We do not go to British Association meetings to sit for hours together to hear papers read such as we have listened to *ad nauseam* during the previous sessions—our main object is to meet and exchange views; but everything seems to be done to prevent rather than to promote this. Far fewer papers should be read; far more care should be devoted to the selection of papers; much more should be done to encourage discussion, especially between Sections; and ample time and opportunity should be given for conversation.

The Sectional Committees are absurdly unwieldy bodies, and in the case of some Sections, practically comprise the entire Section: an appeal was made to the Council by my Section to put a stop to a practice which enables all the nobodies to become members of the Sectional Committee, but without result: I believe we were told that we could do as we liked. Had this been the case, we should scarcely have troubled the Council. The Sectional officers, with at most half a dozen other members, would form a far more useful Committee than any larger number; but if it be thought otherwise, let the whole Section sit as a Committee.

Lastly, a word may be said as to the date of meeting. Could any time be more unsuitable than the beginning of September? Most of those who are engaged in advancing science are then in the very middle of their holiday, and can attend only at grave personal inconvenience. HENRY E. ARMSTRONG.

The Mode of Observing the Phenomena of Earthquakes.

THE publication of Mr. Davison's paper "On the Study of Earthquakes in Great Britain," in NATURE of the 7th inst. (p. 346) furnishes me with an opportunity of making a few *remarks*, followed by a *suggestion* as to the mode of recording the effects of seismic disturbances of the earth's crust on the apparent change of position, especially of vertical objects, in the field of vision of the observer.

Remarks.—It will, I think, be admitted that the descriptions of the alleged rocking to and fro of walls, towers, and chimneys, may not unfrequently convey an exaggerated idea of what really takes place; and, probably, the same is true of the narratives of personal experiences of reeling or rolling movements on the part of the narrator. I refer, of course, to the alleged *extent* of these movements, for no one can doubt their actual *occurrence* as the result of a *tremblement de la terre.* Such composite structures as walls, towers, and chimneys have a real flexibility and elasticity, as is shown, for example, by the opening and shutting up of cracks and fissures in their substance. But the extremely vivid accounts which we read of the swaying to and fro of solid buildings, as witnessed by persons in the upright position, and by others who are recumbent, suggest at least that some of these recorded disturbances of position in external objects may be more apparent than real, and may depend on some sudden uncontrollable movement of the head, and therefore of the optic axes of the observer's eyes.

It is well known that, when the head is moved swiftly to one side and back again to a vertical position, upright objects. seen in front, appear to shift from their vertical position in an opposite direction, and then back again. It is not here needful to explain scientifically this very obvious phenomenon. A similar apparent displacement of objects, though in a vertical direction, occurs when the head is nodded backwards and forwards. Movements of the head in intermediate directions produce intermediate effects; whilst rotatory movements of the head give rise to corresponding though mixed kinds of disturbance of objects in the field of vision. Lastly, if the observer is in a horizontal position, as in bed, for example, a sudden rolling over of the head to one side and back again produces like phenomena.

Now such disturbing movements of the optic axes must frequently occur in the case of persons suddenly subjected to the consequences of earthquake tremors, whether such persons are in a vertical or in a recumbent position; and it is difficult to understand how they should not *occasionally* seem to exaggerate the apparent effects of the disturbance of the earth's surface and the objects planted upon it. The equilibrium of the observer's head is suddenly disturbed in a given direction, and an opposite involuntary movement instantly occurs in order to restore the previous condition of things. Granting, then, the *objective* reality of the swaying movements of vertical structures during earthquakes, there seems to me to be reason to think that the effect of these is occasionally enhanced, and their record influenced by the *subjective* impressions due to movements occurring in the observer's own optical apparatus.

Suggestion.—Supposing this view to be correct (though I can furnish no direct proof of its truth from earthquake records), it appears to me that the *suggestion* of which I spoke at the commencement of this letter would be a useful addition to paragraph (*a*) of Section 2, Division A, of Mr. Davison's paper (p. 348), which relates generally to the "situation of the observer." This suggestion is that it should always be noted and stated towards which *point of the compass* the observer's face was directed at the moment of each observation, concerning the deflection of upright buildings, rocks, and so forth, especially of their lateral deflections. For it is obvious that if a sufficient number of such observations were recorded, it ought to happen, on my hypothesis, that persons who looked *across* the earth-waves would be moved up and down, and thus would have the vertical movements only of objects in front of them exaggerated, whilst persons who looked along the waves would be swayed sideways by the undulations of the soil, and would therefore have the extent of the lateral movements apparently increased. Under the former condition, the "little hills" might appear to dance; in the latter case, cliffs, towers, walls, and chimneys might seem to sway inordinately from side to side.

Many such observations, duly recording the variations in the apparent *extent* of the movements noted, together with the *positions* of the observer as regards the compass, would, when

compared with the ascertained direction of the earth-waves, confirm or upset my general supposition. But, if this were found to be correct, such observations would furthermore constitute, even in the absence of special seismic instruments, a certain amount of evidence as to the actual direction of the earth-waves on any particular occasion.

Similarly, a record of the exact direction of recumbent observers in regard to the points of the compass, might, when compared with their respective descriptions of the movements of objects about them, serve a similar purpose.

Man himself would thus to a certain extent—that is, as regards the local direction of the earth-waves—be his own seismometer. Possibly, some evidence on this subject might even now be obtained by comparing the descriptions of the appearances with the ascertained directions of the outlook of different observers. JOHN MARSHALL.

92 Cheyne Walk, Chelsea.

On a Problem in Practical Geometry.

IN treatises on practical geometry rules are given by which an arc and its chord or an arc and its tangent may be divided proportionally, but they leave an error which is often too great.

By the following method the points of division move step by step towards their required positions until errors are of less than any assigned amount.

Let GMH be the chord (Fig. 1), M its middle point, AOB the perpendicular diameter. In AOB produced take a series of points B'B''B'''..., determined thus: BB' = BG, B'B'' = B'G... Then evidently circles with centres at BB'B''..., passing through G, form a series of which each has on its circumference the centre of the succeeding one. These circles cut the line AM in a series of points A'A''..., and the arcs

FIG I.

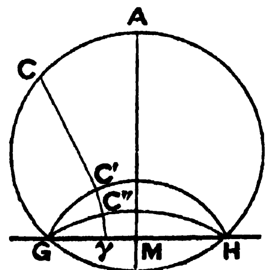


FIG 2.

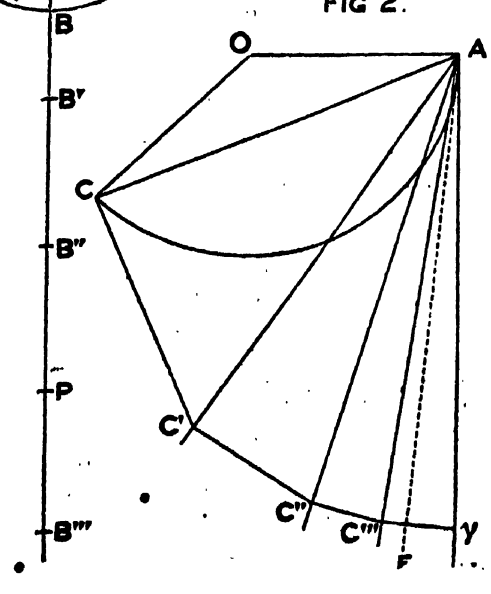

GAH, GA'H, GA''H... get rapidly nearer the straight line GH. Any point C on the given arc GAH may now move to its destination γ on the line GH by stepping up to each circle in the direction of its centre; along a path CC'C''..., made up of CC' tending to B, C'C'' tending to B', and so on.

That all the arcs which this path crosses and the chord to which it tends are divided proportionally at the points CC'C''... γ follows from the almost obvious theorem that if the centre of one circle is on the circumference of another, lines drawn from that centre intercept arcs of the circles having a constant ratio.

If the circles become inconveniently large before the required approximation is reached, we may use the following: C'C''... are the centres of the circles inscribed in GCH, GC'H..., which are easy to construct. Also it may be noticed that the angle made with AO by each of the parts of CC'C''... is half that made by the preceding part, and the process may be brought to an end at any stage with progressive accuracy by making the last angle one-third instead of half of the preceding one.

In Fig. 1 the process is closed after the second stage by drawing the last line (C''γ) not towards B'', but towards the middle point P of B''B'''. This may be done as soon as the last arc GC''H comes to be less than a quadrant.

When the chord becomes the tangent AT at A, the points AA'A''... coincide, all the circles have AT touching them at A, the radius of each is half that of the succeeding one, the arcs intercepted AC, AC', AC''... are equal, and so we get in the limit Aγ, the length of the arc AC laid out on the tangent.

But in Fig. 2 an alternative construction is shown. Bisect TAC by AC', TAC' by AC'', and so on. Draw CC', C'C''... at right angles to AC, AC'... The process is shown closed after the third stage by drawing C'''γ at right angles, not to AC''', but to a line AF such that C'''AF is one-third of C'''AT. In the result Aγ is equal to arc AC.

JOHN BRIDGE.

Caught by a Cockle.

I HAVE often intended writing to you describing a curious occurrence which I witnessed on the coast of Queensland in September 1889, but I have as often forgotten to do so when the opportunity came. While out shooting, along a sandy beach, I noticed a small muddy patch just covered by the rising tide. In this I observed a bird, a sand-piper, which seemed to be striving in vain to rise. I could not think how the bird had become caught, but on coming up to it I found that one claw of one foot was firmly held by a large cockle (about $1\frac{1}{2}$ in. by 2 in.). Of course the bird would have been drowned eventually (though the benefit to be derived by the cockle seems rather problematical); and though it seemed to be aware of its danger, yet it had made no attempt to free itself by trying to bite through the claw, as one sometimes reads of animals doing when caught in traps. As I believe this is rather an uncommon incident, I must make that my excuse for troubling you. D. MCNABB.

H.M.S. *Dart*, New Hebrides, July 3.

ON STELLAR VARIABILITY.

ON the hypothesis of the meteoritic origin of the various orders of cosmical bodies there is a grand and orderly variation, both in light and colour, in the case of every undisturbed swarm during its condensation from its most nebulous condition to that of a cool dark globe.

As by virtue of the ordinary evolutionary process an *undisturbed* swarm successively passes through the changes the results of which define the various groups, the light will wax through Groups I. to IV., and then wane till it is finally extinguished; at the same time the colour sequences will be successively passed through. But with such a variability as this, compared with the period of which our *annus magnus* is but a point of time, we have now nothing to do. We have to deal really with *disturbed* swarms or with double or multiple swarms through their various stages of condensation.

Let us take the purely disturbed swarms first. Imagine a nebula, sparse, and therefore so dim as hardly to be visible at all. Then, further, imagine the appulse of another, or the approach of a meteoritic stream. We shall have the condition which must bring about increased luminosity; the outburst may be short or sudden; the greater luminosity may last a short or a long time; the dying down of the light may be fast or slow. In that we shall have the possibilities of new and dying stars.

If the spectrum of the light produced by this clashing be observed, we may not have precisely the same phenomenon as that observed in the various groups defining

the result of the orderly condensation of a single swarm, for the simple reason that we shall have two swarms or bodies to deal with. Even if the very highest temperature is reached, we shall not have *exactly* the same spectrum as that presented by Group IV.

The most stupendous case illustrating the above remarks is to be found in the Pleiades, the true structure of which has been revealed to us by Mr. Roberts. The principal stars are not really stars at all; they are simply *loci* of intercrossings of meteoritic streams, the velocities of which have been sufficiently great to give us, as the result of collisions, a temperature approaching that of α Lyræ, so far as we can judge by the spectrum; but that the α Lyræ conditions are not present is evidenced by the fact that in Pleione the broad dark hydrogen lines have a bright thin line running down their centres, indicating that we have intensely-heated hydrogen outside that which is absorbing.

So long as these meteoritic streams are interpenetrating and disturbing each other, so long the Pleiades will shine; but their light may soon cease if the disturbance comes to an end, for we are not dealing with masses of vapour like α Lyræ. Indeed, one of them seems to have already become invisible. Of the seven daughters of Atlas, one has disappeared. The "septem radiantia sidera" are seven no longer. The seventh had vanished before the time of Aratus.

"The Pleiades; small the region
They fill, and pale the light they dart.
Seven journeyers men call them
Though only six are visible to ken.
No star, I wis, has vanished from Heaven's floor
Within mortal tradition, and idly is that number
Fabled. Natheless seven the names they bear:
Alcyone, Merope, Celæno, Electra,
Sterope, Taygete, and stately Maia."[1]

At the beginning of the action to which I have ascribed the present light of the Pleiades, we should have the appearance of a "new star," and the greater the light produced and the more sudden the outburst the more certainly would the appearance of a new star be chronicled. Many such stars have burst forth, and the phenomena recorded have been entirely in harmony with the explanation afforded by the hypothesis; but, as the discussion of these phenomena is not yet complete, I shall not in the present article touch further upon them; but I may point out that, before the existence of "variable stars" was recognized, as it is now, the increase in magnitude of a variable at maximum, rendering visible to the naked eye what was before invisible, was attributed to the creation of a new star. Hence it is that the first work done on the periodicity of variable stars grew out of observations of so-called Novæ.

Leaving on one side, then, any question of Novæ, we will inquire into the growth of our knowlege of stars the light of which is known to wax and wane with more or less regularity, and see to what causes this variability has been ascribed. We have to consider those shorter periods of light-variation, well within human ken, light-changes which, instead of taking millions and perhaps billions of years, are undergone in a few days, or weeks, or months. Such changes have been abundantly chronicled from the earliest times and acknowledged to be among the most mysterious phenomena presented to us in the skies.

In this historical survey we must first consider the case of Mira or o Ceti. It is now nearly three centuries ago since Fabricius noticed this star (August 1596), thinking it to be a *nova*, and watched its disappearance in the following October.[2]

Not only Fabricius but Kepler looked upon Mira Ceti as a new star similar to those of 1572 and 1604. Indeed, it was regarded as such until 1638, when some observations by Phocylides Holwarda brought out for the first time the fact that the changes in magnitude repeated themselves. The work done by this astronomer is quoted by Hevelius.

[2] Kepler, "De Stella," chap. xii. p. 112.

Holwarda first observed the star in December 1638, when it was brighter than a third magnitude; he watched it decrease to the fourth, and disappear during the summer of 1639. On December of the same year he again observed it. There is no doubt, indeed, that Holwarda was the first to demonstrate by these observations that the light of stars is liable to periodic changes in intensity.

Fullenius, a teacher of mathematics at Franecker, was the next to observe Mira. He noted that the star was visible on September 23, 1641, and the same date in the following year. In August 1644, however, no trace of it could be made out.

Junquis, a professor at Hamburg, recorded that Mira was of the third magnitude on February 18, 1647, and was invisible from July 1648 to November of the same year.

It was Hevelius, however, who made the first detailed investigation into the variations of the light of this star. Beginning in January 1648 he assiduously watched the changes in magnitude until March 1662, and placed the question of variability beyond the possibility of a doubt.

During the fifteen years of observation Hevelius saw the star go through its changes in magnitude many times, and noted that it was always invisible for several months in the year. He did not, however, determine the period, although it will be seen that the following observations would have been sufficient for him to have deduced an approximate value:—

Sept. 10, 1660—"Instar stellæ 4 magn. fere."
Aug. 20, 1661—"Vix quartæ magnitudinis extitit."
Interval, 344 days.
Sept. 20, 1660—"Æqualis illi in ore Ceti."
Aug. 29, 1661—"Æqualis illi in ore Ceti."
Interval, 353 days.

The determination of the period of Mira Ceti was deduced by Bouillaud in 1667 from all the observations which had been made from its discovery in 1638 to 1660. This discussion occurs in a rare book having the title "Ismaelis Bullialdi ad Astronomos monita duo: Primum de Stella Nova, quæ in Collo Ceti ante annos aliquot visa est. Alterum, de nebulosa in Andromedæ cinguli parte Borea, ante biennium iterum orta."

A review of the book appeared in the first volume of the Philosophical Transactions (p. 381), from which the following account of Bouillaud's conclusions have been taken:—". . . That one *period* from the *greatest phase* to the next consists of 333 days; but that the interval of time betwixt the times of its beginning to appear equal to stars of the *sixth magnitude*, and of its ending to do so consists of about 120 days; and that its *greatest appearance* lasts about fifteen days: all which yet he would have understood with some latitude.

"This done, he proceeds to the investigation of the causes of the vicissitudes in the emersion and disappearance of this star, and having determined that the apparent increase and decrement of every lucid body proceeds *either* from its changed distance from the eye of the observer, *or* from its various site and position in respect of him, whereby the angle of vision is changed, or from the increase or diminution of the bulk of the lucid body itself; and having also demonstrated it impossible that this star should move in a *circle* or in an *ellipsis*, and proved it improbable that it should move in a *strait line*, he concludes that there can be no other genuine, or at least no other more probable cause of the emersion and occultation than this: That the bigger part of that round body is obscure and inconspicuous to us, and its lesser part lucid, the whole body turning about its own center and one axe, whereby for one determinate space of time it exhibits its lucid part to the Earth,[1] for

[1] Here we have the germ of Sir Wm. Herschel's reference to the action of varying amounts of spotted surface; Maupertius' idea of rotatory disks; and Prof. Pickering's suggestion of axes of different lengths.

another, subducts it, it not being likely that fires should be kindled in the body of that star, and that the matter thereof should at certain times take fire and shine, at other times be extinguist upon the consumption of that matter. . . ."

This, so far as I know, is the first proposed explanation of stellar variability on record.

The next star in which variability of light was observed was χ Cygni. Kirch's observations made in 1686 and subsequent years were communicated to the Royal Society. He observed the star with the aid of an eight-foot tube in August 1687. It became visible to the naked eye in October, increased in brightness and reached a maximum in November, and finally disappeared. This observer also found that the star had always the same brightness at a maximum, and in assigning it a period of 404½ days, he noted that this duration was irregular.

These observations bring us to the time of Newton, who at once saw that the cause of true Novæ must be distinct from that producing variability pure and simple. He ascribed the sudden appearance of new stars as possibly due to the appulse of comets :—

"Sic etiam stellæ fixæ, paulatim expirant in lucem et vapores, cometis in ipsas incidentibus refici possunt, et *novo alimento accensæ pro stellis novis haberi*. Hujus generis sunt stellæ fixæ, quæ subito apparent, et sub initio quam maxime splendent, et subinde paulatim evanescunt. Talis fuit stella in cathedra Cassiopeiæ quam Cornelius Gemma octavo Novembris 1572 lustrando illam cœli partem nocte serena minime vidit; at nocte proxima (Novem. 9) vidit fixis omnibus splendidiorem, et luce sua vix cedentem Veneri. Hanc Tycho Brahæus vidit undecimo ejusdem mensis ubi maxime splenduit; et ex eo tempore paulatim decrescentem et spatio mensium sexdecim evanescentem observavit."[1]

But with regard to the ordinary variables, he accepts Bouillaud's suggestion, and adds another :—

"Sed fixæ, quæ per vices apparent et evanescunt, quæque paulatim crescunt, et luce sua fixas tertiæ magnitudinis vix unquam superant, videntur esse generis alterius, et revolvendo partem lucidam et partem obscuram per vices ostendere. Vapores autem, qui ex sole et stellis fixis et caudis cometarum oriuntur, incidere possunt per gravitatem suam in atmosphæras planetarum et ibi condensari et converti in aquam et spiritus humidos, et subinde per lentum calorem in sales et sulphura et tincturas et limum et lutum et argillam et arenam et lapides et coralla et substantias alias terrestres paulatim migrare."

Both Montanari in 1669 and Maraldi in 1692 observed that the magnitude of β Persei or Algol was variable.

The information they gave with respect to changes of the star from the second to the fourth magnitude, though important, was not very definite, and it was left to Goodricke, an English astronomer, to discover, in 1782, the periodicity of these variations and to conclude:—(1) "That the star changes from about the second to the fourth magnitude in nearly three hours and a half and then back to the second magnitude again in the same time. (2) That this variation occurs about every two days and twenty-one hours."[2] Flamsteed observed the star in 1696, and found it to be of the third magnitude, and Goodricke, by comparing it with one of his own, deduced the more accurate value of 2 days, 20 hours, 48 minutes, 56 seconds. At the end of the observations Goodricke added the note: —"I should imagine that the cause of this variation could hardly be accounted for otherwise than either by the interposition of a large body revolving round Algol, or some kind of motion of its own whereby part of its body covered with spots or such-like matter is periodically turned towards the earth."

Another variable observed by Goodricke was β Lyræ.

[1] "Principia," p. 525 (Glasgow, 1871).
[2] "Phil. Trans., 1783, p. 474.

His first observations brought him to the conclusion that the star had a periodical variation of nearly six days and nine hours, but a further investigation showed that the true period was twelve days nineteen hours, there being two maxima and minima. At one minimum the magnitude of the star is between four and five, at the other between three and four.

Zöllner, in a relatively recent discussion advances very little beyond the views advocated by Newton. In considering the main causes of variability, he lays the greatest stress upon an advanced stage of cooling, and the consequent formation of scoriæ which float about on the molten mass. Those formed at the poles are driven towards the equator by the centrifugal inertia, and by the increasing rapidity of rotation they are compelled to deviate from their course. These facts, and the meeting which takes place between the molten matter, flowing in an opposite direction, influence the form and position of the cold non-luminous matter, and hence vary the rotational effects, and therefore the luminous or non-luminous appearance of the body to distant observers. This general theory, however, does not exclude other causes, such as, for instance, the sudden illumination of a star by the heat produced by collision of two dark bodies, variability produced by the revolution of a dark body, or by the passage of the light through nebulous light-absorbing masses.

Among modern inquirers Prof. Pickering has been more original in his suggestions. He has shown that the light-curves of some stars may be explained by supposing them to have axes of different lengths, with dark portions at the ends, symmetrically situated as regards the longer axis.

In the following discussion of the cause of variability suggested by the meteoritic hypothesis, I shall divide variability into regular and irregular, defining regularity by constantly recurring maxima and minima on the light-curves.

THE CAUSES OF VARIABILITY SUGGESTED BY THE METEORITIC HYPOTHESIS.

Regular Variability.—All regular variability in the light of cosmical bodies is caused by the revolution of one swarm or body round another (or their common centre of gravity).

In the case of the revolution of one swarm round another an elliptic orbit is assumed, and the light *at maximum* is produced by collisions among the meteorites at periastron.

In the case of the revolution of a swarm round a condensed body, the light *at maximum* is produced by the tidal action set up in the secondary swarm.

In the case of one condensed body revolving round another, the light *at minimum* is caused by an eclipse of one body by the other. This can only happen when the plane of revolution of the secondary body passes very nearly through the earth.

Irregular Variability.—All irregular variability in the light of cosmical bodies is caused (*a*) by the revolution of more than one swarm or body round another (or their common centre of gravity); or (*b*) by the interpenetration of meteoritic sheets or streams.

In the case of the revolution of more than one swarm round another in elliptic orbits, the irregular maxima are caused by differences of period and periastric conditions

So far as I know, the only previous explanation of variability on such a basis as the one above stated, which assigns the revolution of one mass round another as a cause of variability, is the one we owe to Newton, who suggested that such stellar variability as we are now considering was due to conflagrations brought about at the maximum by the appulse of comets; and no doubt his

idea would have been more thoroughly considered than it has been hitherto, if for a moment the true nature of the special class of bodies we are now dealing with had been *en évidence*. We know that some of them at their minimum put on a special appearance of their own in that haziness to which I have before referred as having been observed by Mr. Hind. My researches show that they are all nebulæ in a further stage of condensation, and such a disturbance as the one I have suggested would be certain to be competent to increase the luminous radiations of such a congeries to the extent indicated.

Some writers have objected to Newton's hypothesis on the ground that such a conflagration as he pictured could not occur periodically; but this objection I imagine chiefly depended upon the idea that the conflagration brought about by one impact of this kind would be quite sufficient to destroy one or both bodies, and thus put an end to any possibilities of rhythmically recurrent action. It was understood that the body conflagrated was solid like our earth. However valid this objection might be as urged against Newton's view, it cannot apply to mine, because in such a swarm as I have suggested, an increase of light to the extent required might easily be produced by the incandescence of a few hundred tons of meteorites.

I have already referred to the fact that the initial species of the stars we are now considering have spectra almost cometary, and this leads us naturally to the view that we may have among them in some cases swarms with double nuclei—incipient double stars, a smaller swarm revolving round the larger condensation, or rather both round their common centre of gravity. In such a condition of things as this, it is obvious that, as before stated, in the swarms having a mean condensation this action is the more likely to take place, for the reason that at first the meteorites are too sparse for many collisions to occur, and that, finally, the outliers of the major swarm are drawn within the orbit of the smaller one, so that it passes clear. The tables, which shall be given hereafter, show that this view is entirely consistent with the facts observed, for the greater number of instances of variability occur in the case of those stars in which, on other grounds, mean spacing seems probable.

I propose here to consider the suggested cause of variability somewhat in detail. I will begin with Groups I. and II.

In these groups the variability is produced by the revolution of one or more smaller swarms round a central swarm, the maximum luminosity occurring at periastron, when the revolving swarms are most involved in the central one.

According to the theory, the normal condition is that which exists at minimum, and in this respect it resembles that suggested by Newton—namely, that the increase of luminosity at maximum was caused by the appulse of comets. All other theories take the maximum as the normal condition, and the minimum as a reduction of the light by some cause—large proportion of spotted surface, or what not.

Anything which in the normal minimum condition of light-equilibrium will increase the amount of incandescent gas and vapour in the interspaces will bring about the appearance of the hydrogen lines and carbon flutings as bright ones. The thing above all things most capable of doing this in a most transcendental fashion is the invasion of one part of the swarm by another one moving with a high velocity. This is exactly what I postulate. The wonderful thing under these circumstances then would be that bright hydrogen and carbon should *not* become more luminous, not only in bright-line stars, but in those the spectrum of which consists of mixed flutings, bright carbon representing the radiation.

We may consider three cases of revolution. Taking that first in order which will give us the greatest light range, we find that this obviously will occur in those systems in which the orbits are most elliptic and the periastric distances least.

On the other hand, a mean ellipticity will give us a mean range.

In these two cases, to account for the greatest difference in luminosity at periastron passage, we have supposed the minor swarm to be only involved in the larger one during a part of its revolution, but we can easily conceive a condition of things in which the orbit is so nearly circular that it is almost entirely involved in a larger swarm. Under these conditions, collisions would occur in every part of the orbit, and they would only be more numerous at periastron in the more condensed central part of the swarm, and it is to this that I ascribe the origin of the phenomena in those objects—a small number—in which the variation of light is very far below the normal range, one or two magnitudes instead of six or seven.

Now it is at once obvious that we should get more variability in these early groups than in any of the more condensed ones, for the reason that in the latter we require the conditions either that the plane of revolution should pass through the earth, or that the light of the central star shall be relatively dim.

This point is best studied in relation to Group II.

The total number of stars included in Argelander's Catalogue, which deals generally with stars down to the ninth magnitude, but in which, however, are many stars between the ninth and tenth, is 324,118. The most complete catalogue of variables (without distinction) that we have has been compiled by Mr. Gore, and published in the Proceedings of the Royal Irish Academy (Series II., vol. iv., No. 2, July 1884, pp. 150-163). I find 191 known variables are given; of these 111 are in the northern hemisphere and 80 in the southern hemisphere.

In the catalogue of *suspected* variable stars given in No. 3 of the same volume (January 1885, pp. 271-310), I find 736 stars, of which 381 are in the northern and 355 in the southern hemisphere. Taking, then, those in the northern hemisphere, both known and suspected, we have the number 492. We have, then, as a rough estimate for the northern heavens one variable to 659 stars taken generally.

The number of objects of Group II. observed by Dunér, and recorded in his admirable memoir, is 297; of these 44 are variable. So that here we pass from 1 in 657 to 1 in 7. Of the great development of variability conditions in this group then there can be, therefore, no question.

Further, while by the hypothesis there is no limit to the increase of luminosity, the variability presented by these objects is remarkable for its great range. The light may be stated in most general terms to vary about six magnitudes—from the sixth to the twelfth. This, I think, is a fair average; sometimes a difference of eight magnitudes has been observed; the small number of cases with a smaller variation I shall refer to afterwards. A variation of six magnitudes means roughly that the variable at its maximum is somewhere about 250 times brighter than at its minimum; a variation of eight magnitudes means that it is 1600 times brighter at maximum than minimum.

These values alone would indicate a condition of things in which the minimum represents the constant condition, and the maximum, one imposed by some cause which produces an excess of light. These various conditions having been premised in considering these groups, I will first deal with the nebulæ.

That many of the nebulæ are variable is well known, though, so far as I am aware, there are no complete records of the spectroscopic result of the variability. But bearing in mind that in some of these bodies, such as the Dumb-bell Nebula, we have the olivine line almost by itself; and in others, which are usually brighter, we have the lines of hydrogen intensified, as in Orion; and in others,

more condensed still, the flutings of carbon added, as in Andromeda; it does not seem unreasonable to suppose that any increase of temperature brought about by the increased number of collisions should increase the intensity of the lines of hydrogen or carbon in the spectrum of a nebula.

The observations already accumulated show conclusively that in the nebulæ—even those so far condensed as the one in Andromeda—the temperature is low; in other words, the meteorites are very far apart; regular variability, therefore, would for this reason be very difficult to detect. It is probable, therefore, that in all the cases previously recorded, we are not dealing with the results of rhythmic action, but the interpenetration of nebulous streams or sheets. When, however, we come to the stars—that is, the more condensed nebulæ—in Group I. and Group II., the temperature is higher, the condensation is greater, and the interaction of double or multiple nebulæ can be more easily traced. This fundamental difference of structure between these bodies and stars like the sun should be revealed in the phenomena of variability; that is to say, the variability of the uncondensed swarms should be different in *kind* as well as in degree from that observed in bodies like the sun or α Lyræ, taken as representing highly condensed types.

Since the stars with bright lines, as I have shown, belong to the former group, and since, therefore, they are very akin to nebulæ, we might, reasoning by analogy, suppose that any marked variability in their case also would be accompanied by the coming out of the bright hydrogen lines. This is really exactly what happens both in β Lyræ and in γ Cassiopeiæ. In β Lyræ the appearance of the lines of hydrogen has a period of between six and seven days, and in γ Cassiopeiæ they appear from time to time, although the period has not yet been determined.

Another star of Group I., η Argûs, is also remarkable from the fact that its light varies in the same sort of way. This star is in the southern hemisphere, and during the last twenty or thirty years a considerable discussion has been going on among astronomers as to whether the surrounding nebula is or is not changing its position with regard to the star in question, which has a bright-line spectrum like β Lyræ, and a period not of thirteen days, but of seventy years. The light varies from the sixth to the first magnitude.

Leaving Group I. and coming to Group II., there is one star, Mira Ceti, whose variations in light-intensity may be taken as characteristic. The history of the discovery of this star's variabiltty has already been given. What happens to it in just a little less than a year is this. First, it is of the second magnitude, and then in about eighty days it descends to the tenth, and, so far as observations with ordinary instruments go, it is invisible. In about another hundred days it again becomes visible as a star of the tenth magnitude. It then increases its light to the second magnitude, and begins the story over again. But sometimes at the maximum its brilliancy is not quite constant. That is to say, sometimes it goes nearer the first magnitude than the second. What happens to the light of the star below the tenth magnitude it is not easy to say. What one knows is that to some telescopes it remains invisible for about 140 days or something like that, and then it begins its cycle over again.

I owe to the kindness of Mr. Knott the opportunity of studying several light-curves of "stars" of this group, and they seem to entirely justify the explanation which I have put forward. It is necessary, however, that the curves should be somewhat carefully considered, because in some cases the period of the minimum is extremely small, as if the secondary body scarcely left the atmosphere of the primary one but was always at work. But when we come to examine the shape of the curves more carefully, what we find is that the rise to maximum is extremely rapid: in the case of U Geminorum, for instance, there is a rise of five magnitudes in a day and a half; whereas the fall to minimum is relatively slow. The possible explanation of this is that the rise of the curve gives us the first sudden luminosity due to the collisions of the swarms, while the descent indicates to us the gradual toning down of the disturbance. If it be considered fair to make the descending curve from the maximum exactly symmetrical with the ascending one on the assumption that the immediate effect produced is absolutely instantaneous, then we find in all cases that I have so far studied that the star would continue for a considerable time at its minimum.

Broadly speaking, then, we may say that the variables in this group are *close doubles;* the invisibility of the companion being due to its nearness to the primary or to its faintness.

We now pass from Groups I. and II. to III., IV., and V. These contain the hottest, and therefore brightest bodies in the heavens. They are, moreover, more condensed than those we have considered. On this ground, their normal light cannot be *increased* to any very great extent by any constantly recurring action, but it may be *reduced* by eclipses caused by the revolution of still further condensed secondary swarms. The nearer the primary, and therefore the smaller the period of the secondary body, the more likely is the eclipse to occur regularly. There are several Group IV. stars of this class, notably Algol, to the first observations of which we have already referred.

This body, which is always visible in our latitudes, well illustrates this class of variable. If we take the beginning of a cycle, it is a star of the second magnitude; suddenly in three hours it goes down to the fourth, and then it comes up in another three hours to the second, and goes on again for very nearly three days: and then it goes down again, comes up again, and goes on again for another three days, and so on.

There is another star very like this—a star which is in 81° N. declination, No. 25 in Argelander's Catalogue. The difference between Algol and this is that the rise and fall are a little more rapid. Its light is feeble for about the same time as the other one, but at the bottom the curve is flat, by which I mean that, instead of going suddenly down and coming suddenly up again, it stops at its least luminosity for some little time.

Prof. Pickering[1] has demonstrated by photographs of the spectra of Algol that Goodricke's explanation of its periodical variability is correct, the companion having no light of its own. In the case of the star D. 81° N. 25 there must be luminosity from the star which eclipses the other. And a very beautiful justification of this view has recently been noted, because, although there is no change in the spectrum of Algol, there is a considerable change in the spectrum of the star, the bottom curve of which is flat, showing that probably the companion has an absorbing action of some kind on the light of the central star passing through it or its surroundings. The light practically changes very much as our sunlight would change if it had to pass through the atmosphere of another sun somewhat like itself coming between us.

In Group VI. we again have a new condition. In these stars the light is relatively faint, and the variation is doubtless due to swarms of meteorites moving round a dim or nearly dark body, the maximum occurring at periastron when the tidal action in the swarm is greatest; hence the addition of the light of what we with our solar conditions should term a large comet would make a great difference in the total radiation.

J. NORMAN LOCKYER.

[1] Proc. Amer. Acad. Sci., vol. xvi. p. 17.

SOME POINTS IN THE PHYSICS OF GOLF.

IT is not an easy matter to determine the initial speed of a golf-ball :—but this is so only because the direct processes which have given us so much information about the flight of military projectiles are here practically inapplicable. No doubt, a ballistic pendulum, or a Bashforth chronograph, might after long and tantalizing experiment give us the desired information. If they did, they would give it much more accurately than we are otherwise likely to obtain it. But the circumstances of a "drive" at cricket or golf are so uncertain, even with the best of players, that it would be waste of time, and wanton vexation of spirit, to employ these instruments of precision. Yet the questions involved are of a very interesting kind, not only from the purely physical point of view but also in consequence of the recent immense development of these national games; so that there is considerable inducement to attempt at least a rough solution of some of them.

The following investigation, because based mainly on mere eye-observations usually of a rather uncertain and difficult kind, is offered only as a rude attempt at a first approximation; and I am quite prepared to find myself obliged to modify the results, when new and more accurate information is forthcoming.

My main reason for bringing it forward in such a condition is to enlist if possible (at this, the proper season) a few keen and accurate observers, who may occasionally find themselves in a position to obtain data of real value. Thus I shall devote what might otherwise be considered an excessive amount of attention to the nature of the real *desiderata*, and to the quality and the sources of the more common errors of the estimates which have been kindly furnished to me. Such as they were, however, they enabled me to state to the Royal Society of Edinburgh, on July 20, conclusions as to initial speed, and coefficient of resistance, nearly agreeing with those given below.

The influence of even a moderate wind on the flight of a golf-ball is so very considerable that, in the first part of my paper, I shall consider the flight of a golf-ball in a dead calm only, and when it has been driven fair and true without any spin. In a former article (NATURE, Sept. 22, 1887) I have discussed the effects and the causes of spin. Also I shall confine myself to the "carry," as the subsequent motion depends so much upon purely accidental circumstances. By far the most valuable data connected with the subject are those which can be obtained in calm weather alone, and which bear on the form, dimensions, and duration of the first part of the course of the ball. It is mainly due to the excessive rarity of *perfectly* calm days that our knowledge of the data is so slight.

Under these restrictions, it is somewhat curious to find that the extreme carry of a golf-ball is not very different from that of a cricket-ball. Both may be spoken of as somewhere about 200 yards. But the circumstances of propulsion are in general very different :—for, unless it is specially teed on a slope, or driven with a spoon (in which case its initial speed is necessarily reduced), a golf-ball goes off at a very moderate inclination to the horizon :—while the sensational drives at cricket usually have the unquestionable advantage of a much higher trajectory.

Theoretically, the proper position of an observer who wishes to secure at once all the required data should be some miles to one side of the plane of flight, so that he should see the trajectory, as it were, orthogonally projected on a dark background of cloud. The small size of the ball, even if there were not other insuperable difficulties, makes observations in this way impossible. Hence each distinctive feature of the trajectory must be separately studied; and this implies either a staff of observers, or, what is much less easy to obtain, a player who can make a number of successive drives almost exactly "similar and equal" to one another. I am convinced that many of the great incongruities which I have found among the data furnished to me, even by skilled observers, are due mainly to the fact that the measures of different characteristic features had been made on drives essentially different in character from one another.

Another fertile source of error lies in the too common assumption that, because a gentle breeze only is felt by the players, who may possibly be in the lee of a sand-hill, there is nothing beyond a similar breeze at heights of 60 to 100 feet; whereas, at that elevation there may be a pretty strong wind. Unless attention is most carefully paid to this, the estimates of the position of the highest point of the trajectory are sure to be erroneous.

The desiderata which are of real importance; and which must, if possible, be obtained from one and the same drive :—the air being practically motionless :—are

1. The initial inclination to the horizon.
2. The range (on a horizontal plane) of the carry.
3. The maximum height attained.
4. The horizontal distance of this maximum from the tee, expressed (say) as a fraction of the range (2).
5. The time of flight.

To these we may add, though it is of less importance, and also much more difficult to estimate with any approach to accuracy,

6. The final inclination to the horizon.

These data are not independent :—in fact theory (such as it is) shows several relations among them. But, as no one of them, except the second and fifth, admits of accurate determination, it is desirable to measure as many of them as possible; so that they may act as checks on one another.

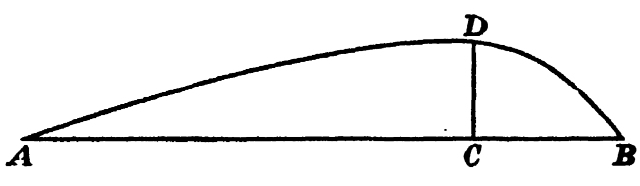
We may also add, what I have recently been endeavouring to obtain :—

7. The horizontal distance passed over in the first second.

This, if properly ascertained, would be one of the most directly useful of the whole set of attainable data.

My experience has been that observers always overestimate the values of the quantities 1, and 6, above :—though they state their ratio fairly well as about 1 : 3. The time of flight, 5, also is usually given too great. But the greatest over-estimate occurs in the case of datum 4. This exaggeration puzzled me very much at the outset of my inquiry. It is easy to see that, in order to produce a path such as that sketched below, in which, (according to estimates sent me from St. Andrews a couple of months ago, when I was unable to procure them myself)

AC : AB : : 3 : 4;



(where D is the highest point of the trajectory) the initial speed and the resistance must *both* be very great. For clearness, the vertical scale is much exaggerated.

Thus I was led to make some experiments with the view of finding an approximation to the utmost admissible initial speed. This I tried to obtain by measuring the speed of the club at impact, and multiplying by 1·6. A hollow india-rubber shell, of the size of a golf-ball, was teed in front of a horizontal axle on which were fixed, six inches apart, two large pasteboard disks with broad borders of very thin white calico. The ball was teed on a level with the axle, midway between the planes of the disks, and three inches beyond their extreme edges. A stout wire, dipped in black paint, projected from the nose of

the club. A drive was then made, in a direction parallel to the axis; first, with the disks at rest; second, when they were revolving about nine times per second. From the result of the first experiment, the correction for the second, due to the fact that the club did not move exactly parallel to the axis, was roughly determined. The results obtained varied within wide limits; *i.e.* from 140 to 700 feet per second for the speed of the club-head at impact. But the majority of the experiments gave from 200 to 300 feet per second. The golfer whose services I enlisted for these experiments, though a very good player, confessed that the novelty of the circumstances had prevented his doing himself justice:—the revolution of the disks, in particular, tending to prevent him from "keeping his eye on the ball." There can be little doubt that the main cause of discrepance among the results was the fact that the correction had to be found when the disks were at rest, and to be applied to data obtained when they were moving. At the time, I formed from these experiments the conclusion that the initial speed of the *ball* must be somewhat over 400 feet per second. I have since been led to believe that this is an under-estimate. I hope when I return to my Laboratory, to carry out this class of experiments with more satisfactory results; by repeating, under favourable conditions, an electrical process which recently failed from the employment of inadequate apparatus.

So long as the speed of a spherical projectile is less than that of sound, it appears that the resistance of the air is at least approximately as the square of the speed. (It is on this account that the effect of even a light head, or following, wind is so considerable. For it is the *relative* speed that determines the resistance, and even a small change in a quantity makes an important change in its square.) Our knowledge of this question is as yet very imperfect; but we cannot fall into any egregious error by making our calculations on the assumption that this law is correct. To apply it, however, we require a numerical datum, *e.g.* the resistance (in terms, say, of the weight of the golf-ball) for unit speed.

Robins, more than a century ago, gave as the result of experiments a statement equivalent to the following:—The terminal speed of an iron sphere in ordinary air is that which it would acquire by falling, *in vacuo*, through a space of 300*d* yards, where *d* is the diameter in inches.

From this it is easy to calculate that the resistance-acceleration of a golf-ball should be about

$$-\frac{v^2}{400};$$

where v is the speed in feet per second, and the denominator is 400 feet.

In the recent edition of *The Bashforth Chronograph*[1] we find that, for an iron shot whose diameter is d inches, and mass w pounds, the acceleration due to the resistance of the air at speed v (expressed in feet per second) is

$$-\frac{118{\cdot}3\,d^2}{w}\cdot\frac{v^2}{1000^2}.$$

It is clear that this expression holds for spheres of any material. For the whole resistance depends only on the size and speed, while the acceleration due to it is inversely as the mass. Now for an average golf-ball $d = 1{\cdot}75$ nearly; and $w = 0{\cdot}101$, because the specific gravity of gutta-percha is nearly the same as that of water. Hence we may express the acceleration by

$$-\frac{v^2}{280}$$

very nearly:—the denominator being in feet.

I have decided to employ Bashforth's result as probably the more accurate:—my own independent estimate, above alluded to, having given 300 in place of 280. It indicates resistance some 43 per cent. greater than that deduced from the older reckoning of Robins. In the formulæ below we will write a for Bashforth's 280 feet.

For a golf-ball not under the influence of gravity the equation of motion would therefore be

$$\ddot{x} = -\frac{\dot{x}^2}{a};$$

which gives, if V be the speed when $t = 0$,

$$\frac{1}{\dot{x}} - \frac{1}{V} = \frac{t}{a},$$

or

$$\dot{x} = v = \frac{V}{1 + \frac{Vt}{a}}.$$

From this we have

$$x = a \log\left(1 + \frac{Vt}{a}\right),$$

and

$$v = V\epsilon^{-\frac{x}{a}}.$$

Thus in general, as $\epsilon^{-0{\cdot}7} = \frac{1}{2}$ nearly, the speed, whatever it be, is reduced to half when the ball has moved through 196 feet, or about 65 yards. The time of passage is 280/V.

In treatises on *Dynamics of a Particle* (Tait and Steele, for instance) it is shown that, for the assumed law of resistance, the approximate equation of a flat trajectory is

$$y = \left(\tan\alpha + \frac{ga}{2V_0^2}\right)x - \frac{ga^2}{4V_0^2}(\epsilon^{\frac{2x}{a}} - 1).$$

In obtaining this result it has been assumed that dx/ds may be treated as being practically unity. This gives a fair approximation to the form of the path of a golf-ball up to, and a little beyond, its highest point; but can scarcely be relied on for the last 30 yards or so of the path, where the inclination to the horizon becomes considerable. But the error will not be a very serious one. If we reject this approximate equation we are forced to use the intrinsic equation of the path, which can be integrated exactly. But, though its use can be made comparatively *simple* by employing a graphic method, it is always very *tedious*, and therefore only to be resorted to in the last extremity; and when we are in possession of data far more exact than any yet obtained. The same may be said, so far as data are concerned, of the elaborate Tables calculated by Bashforth. If we had *accurate* information as to the speed at the highest point of the trajectory, these would give us all that could be desired.

In the above formula V_0 represents the horizontal component of the initial speed:—or, practically, with the limitation introduced, the initial speed itself. α is the angle of projection, and has been carefully determined as on the average about 13°·5. Its tangent is 0·24. Mr. Hodge, to whose valuable assistance I owe this as well as many of my other data, found it absolutely necessary to use a clinometer, as the eye-estimates of the angle of projection are almost always greatly exaggerated. The only other datum required to complete the equation is an approximate value of V. Two methods of finding it were tried, as follows:—

From a number of (necessarily very rough) observations, made by holding to the ear a watch ticking 4 times per second, it seems that in the first second a well-struck ball goes on an average somewhere about 100 yards.

Hence the initial speed must be about

$$280(\epsilon^{15/14} - 1) = 537 \text{ feet per second,}$$

An error of 1 p.c. in this measurement entails 1·6 p.c. error in the result.

The average time of flight seems to be about 4·5 seconds

[1] Cambridge University Press, 1890. For this reference, and for some much needed explanations, I am indebted to Prof. Greenhill.

for a very good drive. As the length of the path is somewhere about 600 feet, the initial speed must be about 468. This, also, is an exceedingly rough estimate, as the effect of gravity has been omitted. The percentage error here is the same as that of the observed time, but has the opposite sign.

Taking them together, these two estimates appear to indicate an initial speed of about 500. Let us for a moment assume this to be the true value, and see how it will agree with the other facts of the case.

Introducing the assumed data, we have for the typical trajectory

$$y = 0{\cdot}258x - 2{\cdot}524(\epsilon^{x/140} - 1).$$

The value of x for the maximum of y is given by

$$0{\cdot}258 - \frac{2{\cdot}524}{140}\epsilon^{x/140} = 0;$$

so that $x_0 = 372$, and $y_0 = 62$, at the highest point of the trajectory. These values, especially that of y_0, agree very well indeed with those independently observed; so that we have a first hint that our assumptions cannot be much in error.

The range (so far as this approximation goes) is to be found by putting $y = 0$ in the general equation. This leads to

$$14{\cdot}31 = \frac{140}{x}(\epsilon^{\frac{x}{140}} - 1).$$

By the aid of a table of values of the function $(\epsilon^x - 1)/x$, which I constructed for the purpose of this inquiry, I find easily

$$\bar{x} = 140 \times 4{\cdot}08 \text{ nearly} = 571.$$

This, again, is a tolerable approximation to the observed range; and, as above stated, we could not expect more. Now nothing in golf is more striking than the well-known fact that, once a player is able to drive a fairly long ball, he secures comparatively little increase in his range by even a great additional exertion. Assuming that the additional effort is well and truly applied (and this is usually, as most men too well know, a *very* large assumption indeed) its only effect must be to increase the initial speed. Let us see how an increase of initial speed to 600 feet per second will increase the range, other things being the same. Performing the calculations as before, the rough equation for the range becomes

$$20{\cdot}165 = \frac{140}{x}(\epsilon^{\frac{x}{140}} - 1);$$

and x is found to be $140 \times 4{\cdot}51$, nearly, $= 631$ feet, or only about 20 yards more. Yet the initial energy of the ball was 44 per cent. greater. So far as this point is concerned, our result is in good accord with experience. On the other hand, if we assume the initial speed to be 400 feet per second only, we find

$$\bar{x} = 3{\cdot}55 \times 140, \text{ nearly}, = 497.$$

This represents a fair, but not an exceptionally good, drive. It thus appears that our assumption, of an initial speed of about 500, meets adequately the requirements of the data for a really fine drive, so far as yet tested.

The ranges for initial speeds of 100, 200, ... , 600 feet per second are, in order, 112, 277, 400, 497, 571, 631. (Had there been no resistance, the ranges would have been as the square numbers, 1, 4, 9, ... , 36.) From these data it would appear that the great majority of golfers give the ball an initial speed of some 200 to 250 feet per second, only:—very frequently not so much, even off the tee:—and that to obtain a carry of double amount, the ball must have nearly quadruple energy.

We may now apply the test supplied by the datum (4). We have, for initial speed 500,

$$x_0 = 372, \bar{x} = 571,$$

so that, in the figure above,

$$AC : AB :: 372 : 571.$$

The ratio is rather *less* than 2 : 3; whereas according to observation, it ought to have been greater; though, of course, always less than 3 : 4. But I do not attach much importance to this discrepancy, as the estimate made of the highest point of the path is at best a rude one, and depends very much upon the position of the observer. For instance, it is almost impossible for him to make even a guess at its true position if it should happen to be situated nearly above his head.

I have calculated a number of trajectories for larger values of *a*, and with V correspondingly reduced, so as to keep the carry the same. But all seem to give too great a value for the maximum height attained; and to place that maximum too near the middle of the carry; to suit the long, raking, drives which have furnished my data. The estimated value, 500 feet per second, of the initial speed in "tall" drives like these, may appear a little startling at first. But anyone who knows how to *cut* a tough ragweed with a thin cane, instead of merely bruising it, as ninety-nine men in a hundred would certainly do at the first attempt, will recognize the sort of *nip* which a really skilled golfer gives at the instant of striking the ball.

It is curious to reflect that it is the resistance of the air, alone, which makes it possible for the legislature to tolerate the game of golf. For the normal drive which was studied above would, but for the resistance of the air, have a carry of 1250 yards (more than two-thirds of a mile) and the ball would fall at that distance with its full initial speed of 500 feet per second! The golfer might deal death to victims whom he could not warn with the most Stentorian "Fore." He could carry, at St. Andrews, from the first tee to the "Ginger Beer" hole! This illustrates, though in a very homely and feeble way, the service which the atmosphere is perpetually rendering us by converting into heat the tremendous energy of the innumerable fragments of comets and meteorites which assail the earth from every side with planetary speeds.

When there is a steady wind, even when it blows in the plane of flight, the mathematical problem is much more difficult:—and this difficulty is not sensibly less when an approximate solution only is sought. For the speed of the wind depends on the height above the earth; and, even if we take the simplest law for this dependence, neither of the equations can be treated separately.

It is easy, however, to see the general nature of the effect. In driving against the wind, the resistance (which of course depends on the *relative* velocity) is greater than in still air:—but its direction is no longer in the line of flight, except at the highest point of the path. It acts in a direction less inclined to the horizon than is the path, and therefore its effect on the horizontal component of the velocity, as compared with that on the vertical component, is greater than in still air. With a following wind, unless it be going faster than the ball, the opposite effects are produced. The general result is to affect the carry considerably, and the vertical motion but slightly. The time of flight is probably a little shortened by a following wind, while it is lengthened by a head wind. The belief, prevalent among golfers, that a ball rises higher against a head wind, and lower with a following wind, than it would do in a calm, is due directly to the effect of perspective:—the highest point of the path being shifted nearer to, or further from, the player. The true effects on the greatest height reached are usually too small to be detected by a casual observer.

The diameter of a cricket-ball is nearly 3 inches, and its weight 5·5 oz. The value of *a* for its motion is therefore 327 feet. Partly on this account, but more on account of its lower speed, a cricket-ball has its path much less affected by resistance than is that of a golf-ball. If we take its maximum initial speed as 130, the initial resistance is only about 1·6 times its weight; while for a golf-ball it rises to about 28-fold its weight. Their momenta are nearly equal, being about 45 and 50 respectively. But their kinetic energy is very different in the two cases, being 90, and 390, foot-pounds respectively. This, again, is in full accord with every-day experience. In the simple vernacular of the cricketer, a well-struck golf-ball would be characterized, at least for the first fifty yards or so of its course, as a "hot" one indeed!

The article may fitly close with a few remarks on another very prevalent fallacy:—viz. the belief that a golfer continues to guide his ball with the club long after it has left the tee. How any player who has ever "jerked" a ball (and who has not?) could maintain such an opinion is an inscrutable mystery. But it is a physical fact, established by actual measurement, that when a block of wood weighing over 5 pounds is let fall on golf-ball (lying on a stone floor) from a height of 4 feet, the whole duration of the impact is less than 1/250 of a second. When it falls from a greater height the duration of impact is less. But if the elastic force which made the block rebound had been employed to move the golf-ball itself, whose weight is only 1/10 of a pound, (or 1/50 of that of the block) the operation would have occupied only 1/50 of the time; say the 1/12,500 of a second. In the case before us we are dealing with much greater speeds, and therefore with still smaller intervals of time. It is with veritable *instants* like these that we are concerned when driving a golf-ball. The ball has, in fact, left the club behind, before it has been moved through more than a fraction of its diameter.

Another way in which this important point can be made plain to anyone is as follows:—When two bodies impinge, the whole time of the mutual compression is greater than that which would be required to pass over the space of linear compression with the relative speed, but less than twice as great. And the time of recoil is greater than that of approach in the ratio 1 : *e*:—where *e* is the "coefficient of restitution" which, with hard wood and gutta-percha, is about 0·6 when the relative speed is very great. Hence the whole time of impact between the club and the ball is that in which the club, moving at 300 feet per second, would pass through about four times the linear space by which the side of the ball is flattened.

P. G. TAIT.

THE WORKING EFFICIENCY OF SECONDARY CELLS.

UNDER this title a paper was contributed, at the recent meeting of the Institution of Electrical Engineers at Edinburgh, by Prof. Ayrton and Messrs. Lamb, Smith, and Woods, which contains some considerable additions to our knowledge of the subject of secondary cells. The cells on which the tests were made were of the 1888 E.P.S. type, and were charged and discharged at the maximum working currents, these being kept constant in value by hand and automatic regulation. In the most important series of tests the limits of volts employed was 2·4 volts for charge and 1·8 volt for discharge: it was found that a lower limit than this led to detrimental actions in the cells, with loss of active material.

The advantages of a constant current are that it is a nearer approximation to practical working conditions, and that the calculations are much simplified: in fact, the ampere efficiency is got by simply multiplying together the ratio of the charge and discharge currents and the ratio of the times occupied in charging and discharging. The true (or watt) efficiency was found by plotting time readings of the P.D., and taking the ratio of the areas of the curves thus drawn: this, multiplied by the ampere-efficiency, is the required true efficiency.

The first important point brought out in the paper is the importance of the resuscitating power possessed by accumulators. In an early set of tests, made on well-charged cells, the authors found a quantity efficiency of over 100 per cent. with correspondingly abnormal watt efficiency, and this, although the tests occupied five days, from which they conclude that, "if accumulators be well charged up before being tested, five days' continuous alternate charging and discharging with the maximum currents allowed by the manufacturers fails to give the normal working efficiency."

Since these results were so unsatisfactory, some method of avoiding drawing on a previous store had to be adopted. Some experimenters secured this condition by running down a cell, and then leaving it short-circuited for some time. In the present series of experiments the required condition was fulfilled as follows: the cells were continuously charged and discharged with regularity until the successive charges occupied exactly the same time, and successive discharges did also. When the cells arrive at such a "steady state," it can evidently be taken that no drawing on a previous store is taking place. It was, then, under these conditions that the experiments were made.

As such a long series of experiments would entail much labour in keeping the current constant, an automatic regulator was devised to effect this, together with further automatic devices for breaking circuit when the P.D. reached any predetermined value, and for telling the time when such break occurred. The authors state that these apparatuses worked to within ½ per cent. of the supposed limits. Throughout the investigation D'Arsonval instruments were adopted, and by suitably suspending the movable coil, the calibration curve was absolutely a straight line. In these further tests the same instrument was used for measuring volts and amperes, the requisite alteration of circuit being made by a rocking commutator. The volts were read frequently, and curves of P.D. plotted. With this apparatus and measuring instruments, the curves given below for steady state of

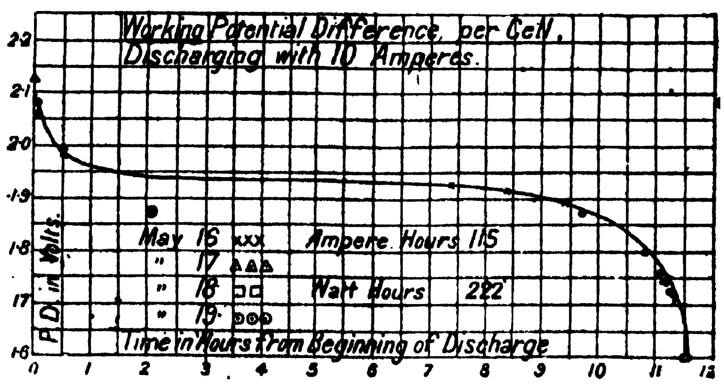


FIG. 1.

charge and discharge between limits of 2·4 and 1·6 volts per cell were obtained.

From these curves efficiencies of 98·3 per cent. for current, and 86·5 per cent. for energy, were obtained.

It was then found that 1·6 volt was far too low a limit to take, as scaling of the plates took place, and so (as mentioned above) limits of 1·8 and 2·4 volts were adopted. After several charges and discharges, the cells arrived at a "steady state" again, the successive times being as follows:—

Discharges. h. m.		Charges. h. m.
10 10	... ...	11 38
10 10	... ...	11 37
10 11	... ...	11 37

"showing to what an absolutely definite state cells arrive after a definite cycle of charge and discharge between fixed limits has been repeated continuously, without interruption, for some weeks." These results give an ampere efficiency of 97·2 per cent. and an energy efficiency of 87·4. These they adopt as the true steady values for this type of cell, and this shows a working storage capacity of 21,380 foot-pounds per pound of plate.

The next point brought out is the effect of rest on a charged cell; the cells were fully charged, and allowed to rest in that state, being well insulated from everything. In every case the first discharge and charge show a marked falling off in capacity and efficiency, the latter being reduced to 58 per cent. in one case cited. A point of some theoretical interest is brought out in connection with the curves obtained in this part of the investigation: a normal discharge curve *falls* rapidly at first, then remains constant, and falls again, as shown in Fig. 1;

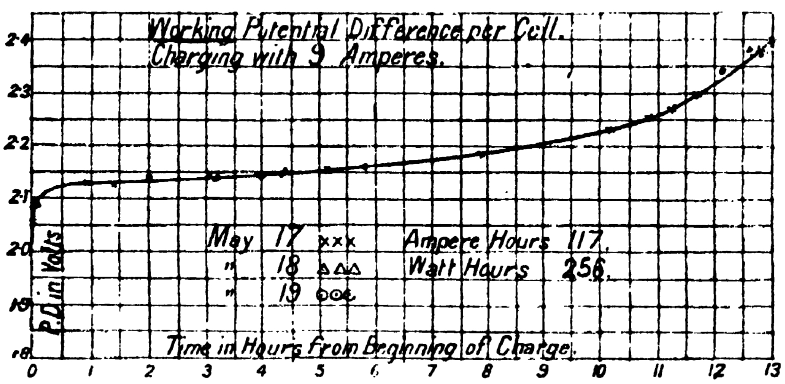

FIG. 2.

the first discharge curve, *after rest*, *rises* at first instead of falling.

The authors sum up this part of their paper as follows:—

"From all that precedes, it follows that the previous history of an accumulator produces an enormous effect on its efficiency. If, for example, an E.P.S. accumulator be over and over again carried round the cycle of being charged up to 2·4 volts per cell and discharged down to 1·8 volt per cell, the charging and discharging currents being the maximum allowed by the makers—viz. 0·026 ampere per square inch in charging, and 0·029 ampere per square inch in discharging—the '*working efficiency*' thus obtained may be 97 per cent. for the ampere-hours and 87 per cent. for the watt-hours. If, on the contrary, the cell be constantly charged up before being tested, then for the first few charges and discharges between the above limits, and with the same current-density in charging and discharging, even the *energy* efficiency may be as high as 93 per cent.; whereas, if the accumulator has been left for some weeks, then, although it was left charged, the energy efficiency for the first few charges and discharges will be as low as 70 per cent.

"While, on the one hand, our tests show that continued rests of a charged accumulator appear to be far more serious for the accumulator than we had previously imagined, the working efficiency appears to be higher than has hitherto been supposed, since we believe that about 84 per cent. efficiency in the watt-hours is all that the advocates of accumulators have claimed for them."

The next section deals with some points connected with the chemical action, and it is shown that the actual amount of SO_3 liberated on charge per ampere-hour, as calculated from the change of specific gravity, agrees well with the ordinary simple formulæ. We understand a further paper on this point may probably be forthcoming later on, which will deal with the chemical changes going on in the plugs at various points in the charge and discharge. As this involves the partial destruction of a cell, and a lengthy series of analyses, it was not found possible to put it in the present paper.

The next point brought out is of considerable interest: during several charges and discharges, the difference of temperature between the working cell and a neighbouring idle cell was observed frequently, and it was noticed that the cell cooled during discharge, in spite of the heat generated by the resistance. This was simultaneously observed by Prof. Duncan in America. The general shape of the temperature curves is given below.

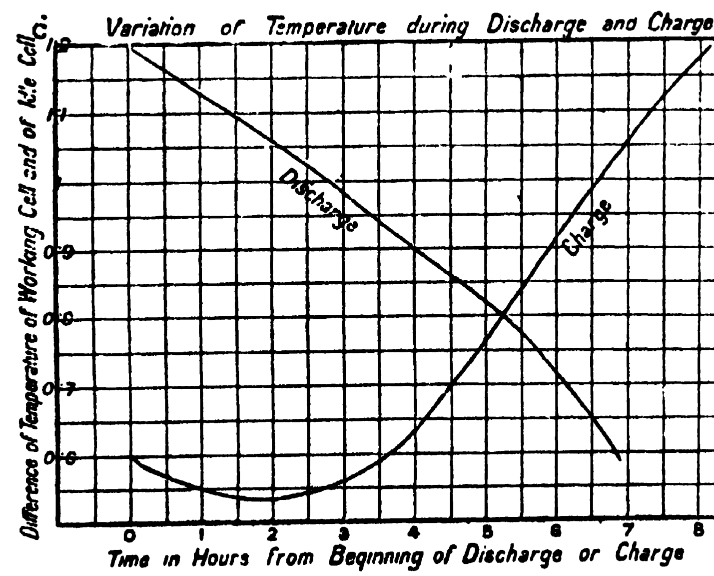

FIG. 3.

From the mean excess of temperature of the cell the authors deduce the somewhat startling fact that 17 per cent. of the energy put into the cell is wasted by radiation and convection. As they found that but 13 per cent. is really lost, it follows that the rest of the energy must be given by some sort of primary battery action, so that they consider an accumulator is partly a reversible and partly an irreversible battery. In this way the gradual deterioration is accounted for. Possibly this may partly account for the short life of small accumulators.

The concluding section deals with the question of the resistance of cells when brought to a steady state. The method adopted is that of introducing an opposing E.M.F. in the voltmeter circuit when time readings of the E.M.F. are being taken on breaking circuit. From these the E.M.F. at breaking circuit is found by producing backwards to zero, and the P.D. being also measured, together with the current before breaking, we

can get the resistance at the moment of break. The method is delicate, and seems to have yielded good results; but lack of time has prevented this section being dealt with with other than one set of current values.

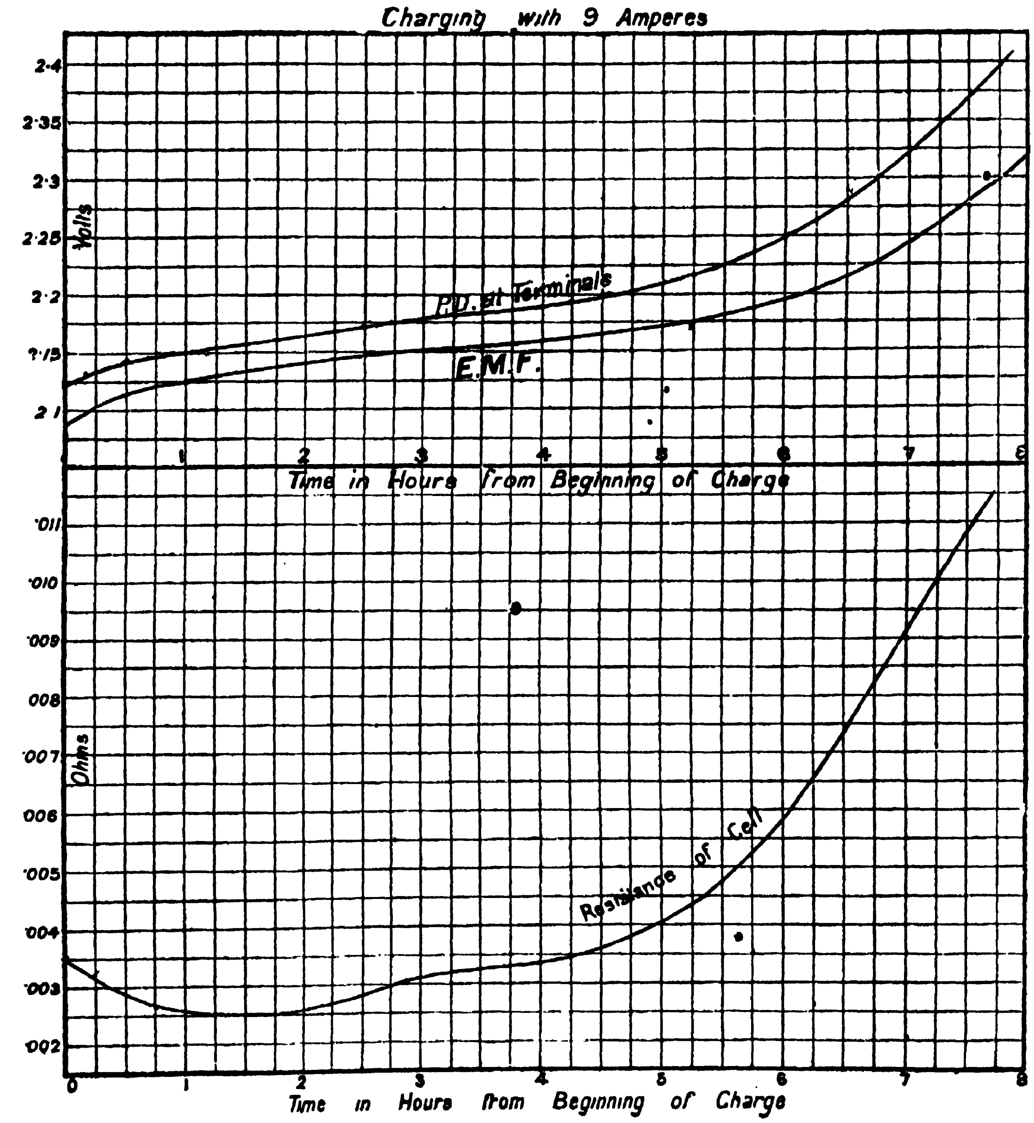

FIG. 4.

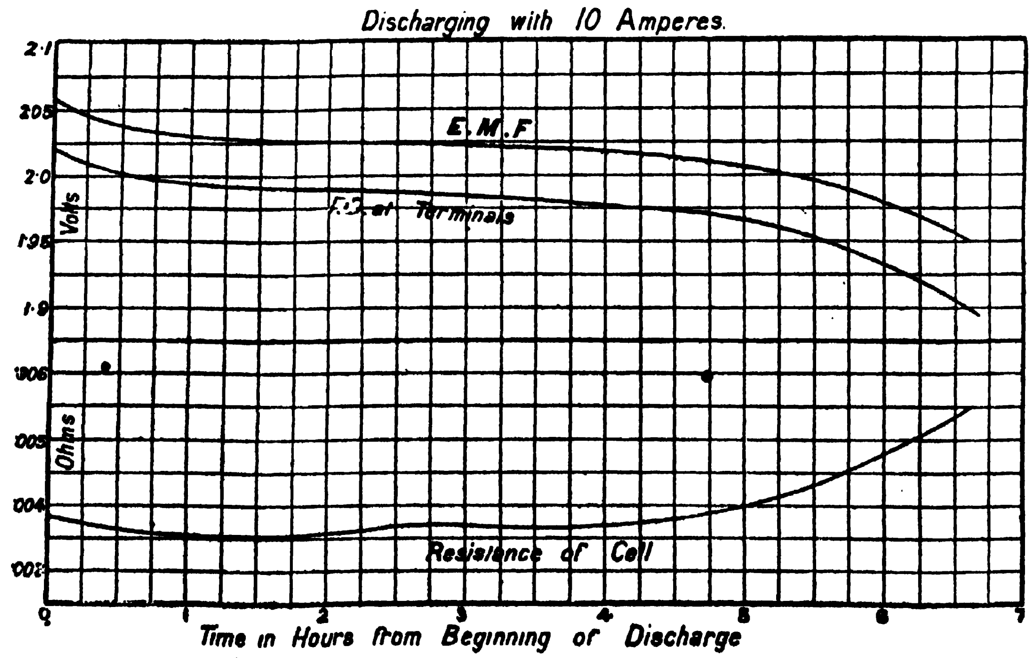

FIG. 5.

We print the curves given in the paper for resistance on charge and discharge.

The paper seems, on the whole, a useful and suggestive contribution to the current knowledge on the subject.

NOTES.

AT a meeting lately held at Stonyhurst College, as we have already recorded, it was decided that a memorial of the late Father Perry should be established. It is proposed either that a new telescope with a 15-inch object-glass shall be erected at Stonyhurst, or that the present equatorial stand shall be furnished with a 15-inch objective. Whichever be adopted, the telescope and the house in which it stands will be called the "Father Perry Memorial," and the work done with the instrument will be published under this name. For the complete telescope and house, £2700 would be required; for the objective alone the sum needed would be £700. It is hoped that funds large enough for the more magnificent monument may be obtained. A more appropriate memorial could not have been suggested, and we have no doubt that many friends and admirers of the late Father Perry will be glad to take this opportunity of expressing their appreciation of his character and work. Subscriptions should be sent either to the "Father Perry Memorial" account, at the London Joint Stock Bank, Limited, Pall Mall Branch, London, S.W., or to Arthur Chilton Thomas, Hon. Secretary and Treasurer, *pro tem.*, Marldon Chambers, 30 North John Street, Liverpool.

THE remains of Captain John Ericsson are now being conveyed across the Atlantic to their last resting-place in Sweden. The transfer of the body, on Saturday, from New York to the war-ship *Baltimore*, was made the occasion of a striking ceremony in honour of the memory of the great inventor. The coffin, wrapped in the flag which floated from Ericsson's famous naval ram, the *Monitor*, in the struggle with the *Merrimac*, was escorted down Broadway by a procession; and among the mourners were the Secretary of the Navy, Admiral Wordon, who commanded the *Monitor* in the engagement with the *Merrimac*; Admiral Braine, commanding the Navy; General Howard, commanding the Army; the Mayors of New York and Brooklyn; and the members of the Swedish Legation. The New York correspondent of the *Daily News* says that dense crowds witnessed the procession, standing with bare heads as it passed. Flags, Swedish and American, were displayed in great profusion throughout the city and harbour. Great bands of streamers festooned fronts of the buildings along the city's main thoroughfare, and from the windows hung colours in endless profusion and variety. The harbour never presented a more charming picture. All the shipping along the water front were dressed for the day with the flags of all nations, at half mast. The body was placed upon a tug at the Battery, and was taken down a long line of shipping to the *Baltimore*, which lay waiting to receive it. The day was rarely beautiful, and the great harbour swarmed with craft of all descriptions. Below the *Baltimore*, stretching in a long line down the bay, were ranged other war-ships. Minute guns were fired till the body reached the ship, when the brief ceremonies of receiving the body were completed. The *Baltimore* then ran up the Royal naval ensign of Sweden, and steamed slowly down the line of battle-ships towards the sea, each vessel raising the same ensign as she passed and firing a salute of 21 guns. The forts at the Narrows also saluted as she passed.

THE meeting of the Iron and Steel Institute in America promises to be very successful. About 300 members and many of their friends will leave England for New York next month. The week beginning on September 29 will be devoted to the reading of papers and discussions by members of the American Institute of Mining Engineers and the English Iron and Steel Institute; and, again, on October 9 and the two following days, these two bodies will co-operate at an international meeting at Pittsburg. Afterwards, excursions will take place to the iron ore and copper regions of Lake Superior and to the new iron-making district of Alabama. The American Reception Committee will provide sleeping and luncheon cars to take their visitors over 3000 miles of the United States.

THE eighth meeting of the International Congress of Americanists will be held in Paris from October 14 to 18. Questions relating to history and geography, archæology, anthropology and ethnography, and linguistics and palæography, have been drawn up by the organizing committee for the consideration of the Congress. Communications regarding the forthcoming meeting should be addressed to M. Désiré Pector, General Secretary of the Organizing Committee, 184 Boulevard Saint-Germain, Paris.

THE American Forestry Association is to meet at Quebec on September 2, and will sit four days. By invitation of the Government of the Province of Quebec, the meetings will be held in the Parliament buildings.

THIS week the Sanitary Institute has been holding its twelfth Annual Congress at Brighton. The business of the Congress was opened on Monday evening, when Sir Thomas Crawford delivered his presidential address in the music-room of the Royal Pavilion, before a large assembly. After a tribute to the late Sir Edwin Chadwick, the president dealt with "some fragments of the story of laws violated to the prejudice of health." On Tuesday an interesting address on "The Living Earth" was delivered by Dr. G. Vivian Poore, President of the Section for Sanitary Science and Preventive Medicine. Mr. W. H. Preece lectured on Tuesday evening on the sanitary aspects of electric lighting.

THE new number of the Journal of the Royal Horticultural Society contains a full and interesting report of the Daffodil Conference held at Chiswick in April last. The Conference lasted two days, and on the first day the chair was taken by Prof. Michael Foster, who, in the course of his opening address, offered some remarks on the naming of different forms of the daffodil. He urged that new names should be given only to forms which can be readily recognized as distinct by ordinary people, and are more beautiful than, or differ in beauty from, their forerunners. A new name should also, he thought, be, if possible, one that can be easily written, and easily read, and that "can be spoken, if not easily, at least without great effort." Mr. J. G. Baker, who presided on the second day, said that twenty years ago very few people took any interest in daffodils, but now the daffodil shared with the primrose the honour of being the most popular flower of the spring-time. "The genus, he added, "is of great interest from a botanical point of view. We are obliged as botanists to deal with all plants on one uniform plan as regards arrangement and nomenclature. From that point of view we look upon *Narcissus pseudo-narcissus* as a single aggregate species, and, comprised within this, there are in gardens about 200 forms. In the whole genus we have only about twelve or sixteen distinct species in this sense. The greatest change at the present time is the raising of forms from species or varieties not known to hybridize before, and it is wonderful that all the Narcissi cross so freely, many of them—as, for instance, *N. pseudo-narcissus* and *N. poeticus*—being so distinct from each other in form."

THE Australasian Association for the Advancement of Science has published a volume containing a report of its first meeting, held at Sydney, New South Wales, in August and September 1888. The editors are Prof. A. Liversidge, F.R.S., and Prof. R. Etheridge, Jun. The volume includes many valuable addresses and papers, and is well illustrated.

THE death is announced of Dr. Felix Liebrecht, an early and highly successful student of folk-lore and comparative mythology.

He was born at Silesia, in 1812, and after studying at Breslau, Munich, and Berlin, became a professor at Liége, where he remained during the greater part of his working life. He translated the "Pentamerone" of Basile from the Italian in 1846, and in the following year issued a version of the romance of Barlaam and Josaphat from the Greek of Johannes Damascenus. In 1851 he translated Dunlop's "History of Fiction." A curious treatise by Gervase of Tilbury attracted his notice as being a sort of encyclopædia of mediæval folk-lore, and he brought out an edition of it in 1856 enriched with many valuable notes. A selection of his contributions to periodical literature on his special subject appeared in 1879, entitled "Zur Volkskunde."

PROF. FLOWER and Mr. Lydekker are engaged in preparing for publication a work entitled "An Introduction to the Study of Mammals, Recent and Extinct." It is based mainly upon the articles contributed by the first-named author and Mr. G. E. Dobson to the ninth edition of the "Encyclopædia Britannica," but much new matter will be added, and the whole brought up to date. The publishers are Messrs. Black, of Edinburgh, and the work is expected to appear before the end of the year.

MESSRS. D. C. HEATH AND CO., Boston, announce the publication of a new number in the series of "Guides for Science Teaching," issued under the auspices of the Bostonian Society of Natural History. The book is entitled "Insecta," and is written by Prof. Hyatt, Curator of the Natural History Society. It is extensively illustrated.

MR. J. B. MARCOU'S "Bibliography of North American Palæontology in the year 1886" has been reprinted from the Smithsonian Report for 1886–87.

THE City and Guilds of London Institute has issued its programme of technological examinations for the session 1890–91. In a special paper attention is called to various alterations and additions.

THE University Correspondence College has published, in its Tutorial Series, a Directory containing all necessary information as to London Intermediate Science and Preliminary Scientific Examinations.

DURING the cruise of the U.S.S. *Thetis* in the Behring Sea and Arctic Ocean, in 1889, several officers were directed to prepare reports on subjects connected with the waters and regions visited by the vessel. One of the reports drawn up in accordance with instructions related to the Eskimos of north-western Alaska, and was written by Mr. John W. Kelly, who had spent three winters among the north-western Eskimos. This report has now been published by the United States Bureau of Education, and all students of ethnography will find in it much that cannot fail to interest them. It is accompanied by English-Eskimo and Eskimo-English vocabularies, prepared by Ensign Roger Wells, chiefly from information furnished by Mr. John W. Kelly. These vocabularies are primarily intended for teachers in Alaska, but it is expected by the Bureau of Education that they will also be of service to officers of the navy and of the revenue marine service, to all Goverment officials in Alaska, to committees of Congress visiting the country, and to many others who for any reason may desire to study the Eskimo language.

THE U.S. Bureau of Education has issued a Bulletin, by Prof. C. F. Smith, of the Vanderbilt University, on "Honorary Degrees as Conferred in American Colleges." The author protests vigorously against the lavish way in which various American institutions raise incompetent persons to the rank of "doctor."

WE have received from the Santiago Observatory (Chile) two volumes comprising the meteorological observations for the years 1882–87. This Observatory, which is furnished with the best instruments, has published observations in the present form since 1873, although they had been taken and partially published for many years previously. The observations for three hours daily are given in a tabular form, and the means for each day are laid down in curves. Full particulars as to the instruments and methods of observation are given in an earlier volume, and the series presents most valuable materials for the study of the climate in those distant parts.

THE Italian Meteorological Office has published its "Annals" for 1886, consisting of four folio volumes. The first volume contains the Report of the Director of this extensive organization, and shows that there were in that year 123 observatories and stations at which complete observations were made, and 630 stations recording temperature and rainfall. This part also contains some valuable memoirs, among which may be mentioned: the climate of Massowah, by P. Tacchini; the comparison of anemometers, and evaporation, by Dr. Ragona; the temperature of snow at different depths, and of the air above it, by Dr. Chistoni, &c. Vols. ii. and iii. contain the ten-day, monthly, and annual means for the various stations, and the results of evaporation and cloud observations. Vol. iv. deals more especially with earthquake phenomena, and contains investigations on several shocks which have occurred in Italy, together with memoirs on the various seismographs used in different countries.

THE Archæological Survey of India perseveres with its unostentatious task of reclaiming from ruin and oblivion the countless inscriptions which lie scattered about India, offering a clue to many questions of ancient history and philology. These despised or neglected records are found in all sorts of likely and unlikely places. The *Englishman* of Calcutta refers to one which has lately been recovered from obscurity, and which is just a thousand years old. It was found incised on a stone slab partly fixed in the wall of a house and used as a seat, in the bazaar of Pahoa or Pihewa, in the Umballa district. Considerable difficulty was experienced in inducing the owner of the house to allow the stone to be removed, but the treasure was eventually acquired, and now lies in the Lahore Museum. The inscription consists of twenty-one stanzas of Sanskrit verse, and is an account of the building and endowment of a temple of Vishnu, together with a eulogy of the family who performed the meritorious deed. Regarding one of the brothers we are told that "when suppliants with rapture looked on his lotus face their mental anxiety completely vanished in an instant; and the crowd of hostile trumpeting elephants always shook before him in battle ready to disperse." This may be taken as a characteristic Oriental rendering of the sentiment of the familiar Scotch song, "His step is first in peaceful hall, His sword in battle keen." For extravagance of laudation, however, a higher place must be given to an inscription found near Jubbulpore, in which it is said of a certain king, that although the tread of his armies roused the apprehension of the three worlds—heaven, earth, and hell—yet there was no dust raised, as the road was flooded by the tears of the captive women who followed in his train.

THE *Photographic News* concludes an interesting article on the photographing of clouds with the following suggestions, which are offered for the benefit of those who have not had much experience in making cloud negatives:—If the sun is to be included in the picture, films or ground-glass backed plates should be used. Any lens which will take a good landscape can be used, and its smallest stop should be employed. As a rule, the exposure will be about one second on a slow plate, but in the case of red sunrises and sunsets, this may often be increased to as much as eight or even ten seconds, unless isochromatic plates are available. The development must be very carefully watched, and not carried too far.

COUNTLESS swarms of rats periodically make their appearance in the bush country of the South Island, New Zealand. They invariably come in the spring, and apparently periods of about four years intervene between their visits. In a paper published in the new volume of the Transactions and Proceedings of the New Zealand Institute, Mr. Joseph Rutland brings together some interesting notes on the bush rat (*Mus maorium*). In size and general appearance it differs much from the common brown rat. The average weight of full-grown specimens is about 2 ounces. The fur on the upper portions of the body is dark brown, inclining to black; on the lower portions white or greyish-white. The head is shorter, the snout less sharp, and the countenance less fierce than in the brown species. On the open ground bush rats move comparatively slowly, evidently finding much difficulty in surmounting clods and other impediments; hence they are easily taken and destroyed. In running they do not arch the back as much as the brown rat. This awkwardness on the ground is at once exchanged for extreme activity when they climb trees. These they ascend with the nimbleness of flies, running out to the very extremities of the branches with amazing quickness; hence, when pursued, they invariably make for trees if any are within reach. The instinct which impels them to seek safety by leaving the ground is evidently strong. A rat, on being disturbed by a plough, ran for a while before the moving implement, and then up the horse-reins which were dragging along the ground. Another peculiarity of these animals is that when suddenly startled or pursued they cry out with fear, thus betraying their whereabouts, an indiscretion of which the common rat is never guilty.

IN a paper recently read before the Vienna Academy, Herren Elster and Geitel give the results of a year and a half's observations of atmospheric electricity on the north side of Wolfenbüttel (bordering an extensive meadow). They used a stand carrying a petroleum flame and connected by insulated wire with an electroscope. A marked difference was found in the phenomena of spring, summer, and autumn, on the one hand, and winter on the other. In the former the daily variation of the fall of potential showed a distinct maximum between 8 and 9 a.m., as Exner found at St. Gilgen, and a distinct minimum between 5 and 6 p.m., whereas Exner found a maximum about 6. In winter there is great irregularity; but a weak minimum occurs about 11 a.m., and a more decided maximum about 7 p.m. It appears to the authors that other factors than humidity, with which Exner seeks to explain the variations, are concerned in the case. When the temperature goes below zero, cold mist being then generally present, there is often rather a sharp rise in the values, the aqueous vapour having then less action. Rainfall in a neighbouring region lowers the fall of potential both in winter and summer, and a disturbance of the normal course will announce a coming change in places still unclouded. Snow, it seems, rather raises the values. It has been shown by Linss that the course of the fall of potential is inversely as the coefficient of dispersion of the air for electricity; which, again, depends not only on the dust and aqueous vapour present, but also, according to Arrhenius's theory, on a sort of electrolytic or dissociative action of the sun's rays on the atmosphere (thus it has been shown that electricity escapes from a conductor under the influence of ultra-violet rays). The authors find their results support this latter view. They consider that the electric processes during formation of precipitates are the chief cause of the disturbance of the normal condition.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss White; a Common Fox (*Canis vulpes*), British Isles, presented by Mr. H. Vane Gladwin; a —— Fox (*Canis* ——) from Buenos Ayres, presented by Mr. J. R. Bell; a Common Otter (*Lutra vulgaris*), British Isles, presented by Mr. W. Corbet; a Punjab Wild Sheep (*Ovis cycloceros*) from India, presented by Dr. W. King; two European Scops Owls (*Scops gui*) from Austria, presented by Mr. Edward R. Divett; six Prussian Carp (*Carassius vulgaris*), British fresh waters, presented by Mr. G. S. Godden; three Pochards (*Fuligula ferina*), Europe, purchased; a Yak (*Poëphagus grunniens*), a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), and three Cambayan Turtle-doves (*Turtur senegalensis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on August 28 = 20h. 28m. 16s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′

(7) X Ophiuchi	Var.	Red.	18 33 7	+ 8 44

Remarks.

(1) This is a fine though small planetary nebula, with four minute stars in close proximity. Lord Rosse described it as "a beautiful little spiral." In 1866 Dr. Huggins observed the spectrum of the nebula, and recorded:—"The spectrum of this nebula consisted of one bright nebulous line of the same refrangibility as the brightest of the lines of nitrogen. No other line was certainly seen." It is evident that this observation has an important bearing on the character of the chief line of the nebula spectrum, and it would be well if some other observer would take the trouble to reobserve it. It should be noted also whether the nebulosity is limited to one side of the line, or is equally visible on both sides.

(2) In 1600, this appeared as a bright star, but it has since been comparatively faint. It is especially interesting from the fact that its spectrum contains bright lines, chief amongst these being the lines of hydrogen and D_3. The Henry Draper Memorial photograph, however, shows in addition a very bright line near λ 447, which Mr. Lockyer suggests, from its association with D_3, is Lorenzoni's *f* of the chromosphere spectrum. It will be remembered that this line occurs also in the spectrum of the Orion nebula. Hence, the lines in the visible part of the spectrum which are common to P Cygni and the Orion nebula are hydrogen (F and G), D_3, and 447 (*f*); another bright line in the violet is also common to the photographs of the two spectra. This similarity is evidently in favour of the view that stars with bright line spectra are similar in constitution to nebulæ, though they are probably more condensed. It will be an interesting inquiry to see if P Cygni has anything more in common with nebulæ in the visible spectrum.

(3) According to the records of the spectrum of this star, it is one of the finest of Group II. Dunér calls it superb, all the bands 2–9 being extremely wide and dark. It affords a good opportunity for further observations of the peculiarities of this class of spectrum.

(4) Gothard states the spectrum of this star as ? II.*a*, whilst Vogel writes it I.*a* (Group IV.). My own observations confirm Vogel's statement, the spectrum being almost like that of α Lyræ.

(5) A star of Group IV.

(6) This is a star of Group VI., showing the secondary bands 2, 3, 4, and 5 (all in the red and yellow) in addition to the bands of carbon. The star is not so red as most of the members of the group, and this is no doubt due to the absorption of red light by the secondary bands. Other details should be looked for.

(7) This Group II. star will reach a maximum about September 5, and the appearance of bright lines, as in other variables of the same type, may be expected. The period is about 300 days, and the magnitude changes from 6·8 to 9. A. FOWLER.

OBSERVATIONS OF SATURN AT THE DISAPPEARANCE OF THE RING.—In a memoir "Sur la variabilité des anneaux de Saturne," published in the *Bulletin Astronomique* (vol. ii. p. 28), M. E. L. Trouvelot touches on some interesting phenomena that he observed in 1877-78, before, during, and after the passage of the sun and earth across the plane of Saturn's rings. On May 18, 1877, M. Trouvelot remarked that the illuminated surface of the ring appeared notably less luminous than the planet; further observations confirmed this, and left no doubt that its relative light diminished up to the passage of the sun across its plane. It was also observed that the colour of the light of the ring appeared yellowish and slightly orange when compared with that of the planet, whereas observations made between 1872-76 indicated that the planet was of a yellowish colour when compared with the ring. The two sets of observations are thus diametrically opposed to each other; and it appears that, when the height of the sun above the plane of the ring is reduced to 4° 30′, the surface of the latter gradually diminishes in light with the approach of the sun to the plane, and afterwards the opposite surface increases in light intensity until the angular distance of the sun from the plane of the ring is again 4° 30′. The cause of this diminution and increase is not well known. It may be due to the change in the angle of incidence of the sun's rays, and, therefore, in the amount of light reflected or to the absorption of the sun's rays by the atmosphere belonging to the rings, or to many other causes.

From October 6, 1877, when the sun was 1° 49′ north of the plane of the rings, to February 6, 1878, when the sun crossed the plane, the illuminated surface gradually decreased in width until it appeared as a thin line difficult to recognize, because of its extreme tenuity. It was observed that the decrease in the width of the illuminated ring appeared to be produced by a shadow slowly obscuring it, and M. Trouvelot attributes the shadow to the existence of a zone elevated above the general level of the ring and slightly inclined towards the planet. To produce the observed phenomenon, a protuberant zone on the ring B, and 6000 kilometres from its outer edge, would have to have an elevation of about 400 kilometres above the plane of the rings: that is, if the north and south surfaces are symmetrical, the thickness of the zone would be 800 kilometres. In consequence, however, of the position of the zone on the ring B, and 25,600 kilometres from the edge of A, the better half of it is generally invisible, hence in practice the thickness may be said to be 400 kilometres, or nearly 249 miles.

Prof. A. Hall has a short note on "The Thickness of Saturn's Ring," in the *Astronomical Journal*, No. 222, and develops the equation by means of which it may be determined. He also notes that Dusejour gives a value equivalent to 958 English miles in his "Traité Analytique," t. ii. p. 127 (Paris, 1789), as the result of a discussion of the disappearances and reappearances of the ring observed before 1789. Herschel, by comparing the thickness of the ring with the apparent diameters of the satellites, found the value 856 miles (Phil. Trans., vol. lxxx. pp. 6 and 7, 1790).

Schroeter found the value of 539 English miles from measurements of the width of the trace of the ring on the ball of the planet ("Kronographische Fragmente," pp. 157 and 211, Göttingen, 1808).

W. C. and G. P. Bond by comparing the amount of light received from the surface of the ring a short time before its disappearance with the light received from *the edge of the ring* found the value <43 miles.

With respect to this latter value M. Trouvelot remarks: "Mais Bond, qui ignorait que le système des anneaux de Saturne n'est pas plan, et que c'est à une assez grand distance de son bord extérieur qu'il atteint son maximum d'épaisseur, ne pouvait arriver qu'à une évaluation erronée et trop petite de cette épaisseur."

Several other points are touched upon in M. Trouvelot's memoir, viz. that Cassini's division appeared more visible on the eastern side of the planet than on the western, when the elevation of the sun above the plane of the ring was between +0° 45′ and +0° 27′; and that the edge of Saturn, like that of Jupiter, was notably more luminous than other parts of the globe. The difference in outline between the preceding and following parts of the ring, the deformation of the limb of the planet at different dates, and many observations possible during the disappearance of the ring are also considered.

The memoir concludes with some remarks and suggestions on the observations that should be made during 1891-92. The next disappearance of the ring is on September 22, 1891, and it will reappear on October 30 of the same year. Again, in May 1892, Saturn will be well situated for observations on the structure of the rings causing the shadow noticed in 1877-78. It is to be hoped therefore that the increased powers now at our disposal will enable many of the questions raised by M. Trouvelot to be definitely settled.

OBJECTS HAVING PECULIAR SPECTRA.—In *Astronomische Nachrichten*, No. 2986, Prof. E. C. Pickering, Director of Harvard College Observatory, notes that an examination of photographs taken during March and April 1890, by Mr. S. J. Bailey, near Closica, Peru, has led to the discovery of some interesting spectra.

A photograph of the spectrum of R Carinæ (R.A. 9h. 29·7m., Decl. −62° 21′, 1900) taken on April 4, 1890, shows that the G and *h* lines due to hydrogen are bright, as in Mira Ceti and other variables of long period.

Two photographs taken on March 19 and 20, 1890, of the star, Cordova General Catalogue, No. 15,177, magnitude 8½ (R.A. 11h. 0·8m., Decl. −65° 1′, 1900), show that it has a spectrum consisting mainly of bright lines, and similar to that of Wolf and Rayet's three stars in Cygnus.

The nebula, General Catalogue, No. 2581 (R.A. 11h. 45·1m., Decl. −56° 29′, 1900) has the same spectrum as General Catalogue 4628. Both these objects show bright lines in the ultra-violet portion of their spectra, which have not been discovered in any other planetary nebulæ.

D.M. +30° 3699, magnitude 9·3 (R.A. 19h. 31·9m., Decl. +30° 19′, 1900), is seen to have bright lines in its spectrum on photographs taken at Cambridge with the 8-inch Draper telescope on June 18, 23, and 25, 1890. The spectrum of this star differs from that of other bright-line spectra of which photographs have been obtained.

ON THE CAPTURE OF YOUNG (IMMATURE) FISHES, AND WHAT CONSTITUTES AN IMMATURE FISH.

SINCE steam-trawling became prominent, frequent complaints of the constant and great destruction of very young fishes by this mode of fishing have been made; indeed, besides the injury to the so-called eggs of food-fishes—then said to be deposited on the bottom—no subject attracted more attention in the Royal Commission of 1883-84—presided over by Lord Dalhousie. Recently the subject has again been urged before the National Sea Fisheries Protection Association—especially by the fish-merchants of London (on the alleged grounds of the diminution in size of the valuable food-fishes)—and, with the assistance of the Board of Trade, an International Conference, to discuss remedial measures "to be taken for the preservation and development of the fisheries in the extra-territorial waters of Europe," was convened in the Fishmongers' Hall. It would be a misapprehension, however, to suppose that those who attended the Conference confined their attention to extra-territorial waters, since the inshore ground (within the three-mile limit) is really more important, *e.g.* in regard to the preservation of certain flat fishes, than the offshore. Thus, as formerly shown, the plaice for the most part passes its early life in the shallow sandy bays of the inshore, and as it attains a length of about fifteen inches it in most cases frequents the deeper water offshore, where it chiefly spawns, the pelagic ova and larvæ being carried shorewards to repeat the process. In the same way multitudes of small turbot, brill, and soles pass their early existence not far from low-water mark on sandy beaches; ling in the barred condition amongst rocks at extreme low-water; and cod, coalfish, pollack, and whiting, near the same regions. Remedial measures therefore, applied, for instance, to the plaice in extra-territorial waters, could only affect the adult or nearly adult fishes, and mainly in regard to the spawning individuals, a point no doubt of vital importance, but which nevertheless does not touch the question before us, viz. the young or immature fishes.

In most modes of fishing as at present followed, young or immature fishes are captured. Thus, in line-fishing a considerable number are hooked throughout the year, and in certain parts of the east coast many in September and October. When we consider the large number of men engaged in line-fishing, and the almost constant nature of such captures, we cannot conscientiously overlook it. The drain on the young cod, haddock,

whiting, ling, and other fishes is a steady one, and though many are replaced in the sea by the fishermen it is doubtful if they will survive. The smaller of the first three, indeed, are generally dead when brought on board. The use of the hook, on the other hand, for the capture of flat fishes—more particularly plaice in sandy bays—contrasts favourably with the work of sailing trawlers on the same ground, since a larger size of fish on the whole is secured; though scarcely a single fish thus obtained is mature. It is probable that the smaller mouth of the pleuronectids prevents the younger forms from so readily taking the hook, the size of which, moreover, would appear to be related to that of the young fishes captured. The liners themselves as a rule the remedy, since they leave the ground frequented by small fishes, *e.g.* haddocks, and seek more mature forms. They appear to be aware that these young fishes haunt the same area a considerable time. This practice cannot be too much commended.

Beam-trawling and otter-trawling, again, are credited with the capture of many young (immature) fishes. In the case of the beam-trawl, now so extensively used, if the meshes of the net be small and work carried on inshore, or where multitudes of young fishes are, large numbers especially of flat fishes are taken. In ordinary steam-trawling for profit, as observed off the east coast in 1884, however, the actual captures of small (immature) fishes were not as a rule serious. For the most part they consisted of common and long rough dabs, neither of which when adult is a large fish, though both, besides other uses, form an important item in the diet of the more valuable fishes. Off Girdleness (Aberdeenshire), however, a considerable number of young cod were captured in autumn, yet every one of these was used as food and was saleable. In the open offshore water very few young plaice are procured, almost all being of considerable size; but in inshore water, *e.g.* in such bays as St. Andrews, vast numbers of small plaice may be captured with a naturalist's trawl (*i.e.* one with a small mesh), and considerable numbers with the ordinary trawl of either sailing or steam trawler, one of the latter in 1884 having about sixty boxes as its catch. Though the very young plaice are abundant at the tidal margin, yet no graduated lines, indicating an increase in size as we proceed outwards, seem to occur, very small forms being found in the outer lines of St. Andrews Bay as well as those approaching low-water mark.[1]

In steam-trawling for profit, the condition of the captured young fishes depends on the length of time the trawl has been down, the state of the sea, and the condition of the bottom. Thus, if the trawl has been at work for five hours the younger fishes are often dead, and, if not, would probably die if replaced in the water, whereas when the trawl of a sailing boat has been down only an hour the majority would probably live if returned to the sea. If the sea be rough, the pitching of the vessel in hauling causes the bag of the net and its load of fishes to strike the side of the ship, and thus the snouts of the fishes are broken and many killed. In the same way soft muddy ground is fatal to the fishes in the trawl, just as in a less degree, the soft sand of the beach proves destructive to trout swept down by a spate.

Shrimp-trawling is another method of fishing proportionally more destructive to young fishes than perhaps any other. As carried on, for instance, in the estuary of the Thames by sailing boats near Canvey Island and towards Tilbury Fort, multitudes of small soles, dabs, plaice, bib, whiting, and other forms, *e.g.* unctuous suckers and *Cotti*, are retained by the small-meshed net, and before the sifting of the shrimps is concluded the majority have succumbed. Nor are hand-nets and the larger ones drawn by horses less destructive. All cause a frequent and great drain on the young fishes, especially in some places on such valuable forms as soles, turbot, and brill, while the food procured for the public is small in comparison with the loss of fish-food. There should be no insuperable obstacle to the immediate substitution of these methods by others less wasteful to fish-life. The French shrimp-trap, for instance, as recommended by Prof. Giard and M. Roussin, is a step in the right direction.

The use of the "sweep-net" on sandy shores for procuring sand-eels is followed by the capture of numerous young cod, green cod, gurnards, whiting, trout, turbot, brill, dabs, plaice, flounders, and other forms. The net has wings of 4-inch mesh, and a centre of strong netted curtain-gauze, so that small fishes are secured in hundreds. The net is worked by two men, one in a boat, the other on shore, and is especially destructive in estuaries. The little fishes thus captured escape the trawls of both sailing and steam-vessels.

The salmon-stake nets, on sandy beaches, secure many small turbot and brill from 5½ inches upwards.

The stow or bag-net for sprats, as used by yawls in estuaries of rivers, is a small-meshed net of great length, fixed to the side of the vessel by the upper beam, and into which immense numbers of young herrings and sprats, and sometimes many sparlings, are swept by the current, besides various round food-fishes, flat fishes, and unsaleable forms, such as *Cotti*, Montagu's suckers, and pipe-fishes, not to allude to an occasional salmon. The captured fishes are now and then used for manure, and much valuable food is thus lost to the community.

The small-meshed sprat-nets (pole-nets) of the Forth are also responsible for great captures of small herrings and sprats for manure, as well as for the destruction of young round fishes, such as cod and whiting. The capture of whitebait in the Thames is another instance of the wholesale destruction of very young fishes.

From the foregoing brief sketch it will be apparent that no special kind of fishing is responsible for the capture of small (immature) fishes, and that legislative measures, to be effectual, must, more or less, cover all. The question, therefore, is beset with difficulties. The prohibition of the landing and sale of such fishes would, of course, shut them out of the market, but it would not prevent their being captured; and while they might be returned to the water as soon as practicable, the mortality, as already indicated, would be considerable. It is difficult to see how, by any modification of apparatus, these small fishes would be enabled to escape capture by liners, trawlers, shrimpers, seine, and other net-fishermen. As recommended to the Trawling Commission of 1884, the mesh of the trawl-net might be enlarged. Thus, for 9 feet at the cod-end, it might have a 2-inch mesh; then, for 12 feet, 2½-inch mesh; next, 3 and 3½-inch mesh; and, finally, a 5-inch mesh towards the beam. The enlargement of the mesh will not altogether prevent the loss of young fishes, but it will diminish it. Moreover, a limit to the time the trawl is down might be considered. The pressure of the larger on the smaller fishes when the bag of the net is hoisted by the derrick, and the swinging of the heavily-laden bag on the side of the ship in rough weather, however, are elements of disaster apparently beyond control at present. If the bag of the net with its fishes could be lifted horizontally into a raft or other apparatus level with the water, much injury to the contents, both young and adult, would be avoided; but the practical difficulties are great. In the other modes of fishing in which young fishes are captured in great numbers, and where restrictive measures are inapplicable, the obstacles would seem to be best met by the modification of apparatus and by the trained intelligence of the master-fisherman.

The question as to what constitutes an immature fish has not hitherto, perhaps, received that strict attention which it merits. In the trawling investigations of 1884 the term "immature" was not used in the strictly scientific sense—that is, in connection with the reproductive organs, though these were examined in all the species. The term, indeed, was purposely employed as nearly synonymous with unsaleable. Recently, Dr. Fulton, the energetic Scientific Secretary to the Fishery Board for Scotland, has had a large number of fishes examined—chiefly by Mr. T. Scott, on board the *Garland*—their sizes and the condition of the reproductive organs carefully noted, and the results, as elaborated by him, are given in a paper about to be issued by the Fishery Board in their Blue-book for 1890.[1] The paper is one of very great interest, and there can be little doubt that the term "immature" ought to be restricted to fishes that have never spawned; and it may thus happen that such may be saleable, *e.g.* in the case of the plaice, brill, turbot, cod, and others. On the other hand, mature food-fishes may be unsaleable from their small size, as in the case of the flounder, dab, and long rough dab, though, as already mentioned, these are important as the food of some of our most valuable fishes. As given by Dr. Fulton the smallest ripe food-fishes procured in the *Garland's* trawl were as follows:—Plaice 12 inches, lemon-dab 8 inches, dab 6 inches, long rough dab 6 inches, flounder 7 inches, craig-fluke (witch) 14 inches, turbot 18 inches, brill 16 inches, sail-fluke 9 inches, haddock 10 inches, whiting 8 inches, cod 20 inches, gurnard 8 inches, and catfish

[1] This appears to differ from the results of the *Garland's* recent work.

[1] I have to thank Dr. Fulton for an early proof, issued, by the sanction of the Secretary for Scotland and the Fishery Board, in connection with the International Conference.

(*Anarrhichas*) 20 inches (?). In most cases these small specimens were males, as in the even more remarkable case of the salmon—in which the milt of a parr a few inches long can be utilized for the successful fertilization of the ova of an adult female salmon. There would therefore be grounds for saying that fishes of a less size than the foregoing are immature. From these observations it will be seen that the minimum size of 12 inches for turbot and brill—adopted by the representatives of the sea-fishing industry of the United Kingdom in June of this year—does not err on the side of excess. Further, since the mature males are often so much smaller than the females, it is apparent that the same restrictive size would not be practicable, though the numbers of the mature females are of greater importance for the welfare of the fisheries than those of the males.

While, therefore, many difficulties beset legislative measures for the preservation of the young fishes, there need be no halt in the efforts of the fishery authorities in investigating the deep-sea fishing grounds far from shore; and this should be carried out as far as practicable and as frequently as possible every month of the year. A comparison of the surface, mid-water, and bottom fauna there with that already known to exist in such bays as St. Andrews could not fail to give valuable and interesting data. Besides, the gaps in the life-histories of the post-larval and young stages of many fishes would thus be more or less bridged over. Finally, there can be little doubt of the expediency of at once providing suitable open-air tanks, *e.g.* at St. Andrews, in communication with the tidal water for the study of the post-larval and young stages of food-fishes, especially with regard to their rate of growth. It has yet to be proved also whether it would be best to place the larvæ of valuable fishes, such as turbot, brill, and soles, in the sea, or to keep them till the post-larval or young stages are reached.

W. C. McINTOSH.

ESTABLISHMENT OF SCIENCE SCHOLARSHIPS.

WE have already called attention to the science scholarships which are being established by the Commissioners for the Exhibition of 1851. The official statement on the subject is as follows:—

In their seventh report to the Crown, presented in July 1889, the Commissioners for the Exhibition of 1851 announced their intention of appropriating an annual sum of not less than £5000 a year to the establishment of scholarships, to enable the most promising students in provincial colleges of science to complete their studies either in those colleges or in the larger institutions of the metropolis, care being taken that these scholarships should be a supplement to, and not in competition with, scholarships already existing through either public action or private endowment.

The decision to restrict the scheme of scholarships to provincial colleges was due to the feeling of the Commissioners that the provinces, which took so large a part in supporting the Great Exhibition of 1851, had a just claim to receive as direct a benefit from the funds derived from that Exhibition as is afforded to the institutions on the Commissioners' Estate at South Kensington, which, although unquestionably of national importance, confer a more immediate advantage on the metropolis.

To assist them in preparing a scheme for the distribution and regulation of the scholarships the Commissioners obtained the services of a committee of eminent men of science—namely, Prof. Garnett, Prof. Huxley, Prof. Norman Lockyer, Sir Henry Roscoe, and Sir William Thomson. To these were added two Commissioners, Mr. Mundella and Sir Lyon Playfair, the latter of whom acted as chairman of the committee.

On the 18th of June last this committee presented the accompanying report on the scope and objects of the scholarships, and it has been adopted by the Commissioners.

The committee then considered the manner in which the scholarships should be distributed. On this point they were bound by the restriction of the present scheme to students in provincial institutions, in which term, however, they suggested that colonial Universities might be comprised. They thought it unnecessary to include in the scheme the Universities of Oxford, Cambridge, and Dublin, in view of the large endowments of those bodies. The committee decided upon the allotment of an annual series of seventeen scholarships in the manner shown by the accompanying list, and the institutions named in the list will be invited to nominate scholars, subject to the conditions laid down in the report of the committee, and provided that they possess scholars worthy of the purposes explained in it.

The present allotment is to be considered experimental and temporary, and the selection now made of institutions to which nominations are offered will be subject to modification in the future, having regard not only to the manner in which the nominations are exercised, but also to the claims of other Universities and colleges which may from time to time be brought under the consideration of the Commissioners.

Provincial and Colonial Universities and Colleges.

Scholarships Annually.		
	1	University of Edinburgh.
	1	University of Glasgow.
Alternately	1	University of St. Andrews (including University College, Dundee). University of Aberdeen.
	1	Mason College of Science, Birmingham.
	1	Bristol University College.
	1	Durham College of Science, Newcastle.
	1	Yorkshire College of Science, Leeds.
	1	Liverpool University College.
	1	Owens College, Manchester.
	1	Nottingham University College.
	1	Firth College, Sheffield.
Alternately	1	Aberystwith (University College of Wales). Bangor (University College of North Wales). Cardiff (University College of South Wales).
In each year	2	Belfast, Queen's College. Cork, Queen's College. Galway, Queen's College. Dublin, Royal College of Science.
		Canada:—
Alternately	1	M'Gill College, Montreal. University of Toronto.
		Australia:—
In each year	2	University of Sydney. University of Melbourne. University of Adelaide. University of New Zealand.
	17	

The following is the first report of the committee for considering the regulation and distribution of the science scholarships:—

The committee have had their attention drawn to the fact that there is a large number of scholarships in the country; that they are increasing at a rapid rate; and, if the Commissioners act on the same lines as those already occupied, it is possible that education will gain little by their action, as the endowment of the Commissioners may interfere with the establishment of new scholarships by private liberality.

Hence it is desirable that the scholarships with which this committee have to deal should be of a higher order than most of those now existing; in fact, their functions should begin where the ordinary educational curriculum ends. This system has been adopted with excellent effects by the French *École pratique des hautes études*.

The committee propose:—(1) That the scholarships shall be of £150 a year in value, and shall be tenable for two years, but in rare instances may be extended to three years by special resolution of the Commissioners. The continuation, each year after the first, shall depend upon the work done in the previous year being satisfactory to the scientific committee which it is suggested shall be appointed by the Commissioners.

(2) That the scholarships shall be limited to those branches of science (such as physics, mechanics, and chemistry) the extension of which is specially important for our national industries.

(3) That the Commissioners shall from time to time select a certain number of provincial and colonial colleges in which special attention is given to scientific education, and give to each

the power of nominating a student of not less than three years' standing to a scholarship, on the condition that he indicates high promise of capacity for advancing science or its applications.

(4) That the Commissioners shall appoint a committee of advice, who will consider and report upon the reasons for which the nominations are made by the respective colleges, and the Commissioners will appoint to the scholarships upon the report of their committee.

(5) That the scholarships when awarded shall be tenable in any University either at home or abroad, or in some other institution to be approved of by the Commissioners. The holder of a scholarship must give an undertaking that he will wholly devote himself to the object of the scholarship, and that he will not hold any position of emolument during its continuance.

LYON PLAYFAIR, Chairman.
WM. GARNETT.
T. H. HUXLEY.
J. NORMAN LOCKYER.
A. J. MUNDELLA.
HENRY E. ROSCOE.
WILLIAM THOMSON.

SCIENTIFIC SERIALS.

American Journal of Science, August 1890.—On the cheapest form of light, from studies at the Allegheny Observatory, by S. P. Langley and F. W. Very. The authors have made a long and interesting series of observations, by means of the bolometer and spectroscope, on the light radiated by the fire-fly (*Pyrophorus noctilucus*, Linn.) found in Cuba and elsewhere. It has been previously shown that in all industrial methods of producing light, like the candle, lamp, or gas, more than 99 per cent. of the energy is, as far as illumination goes, wasted; and in sources of higher temperature, like the incandescent light and electric arc, even under the most favourable conditions, an enormous waste is involved. The study of the radiation of the fire-fly demonstrates that it is possible to produce light without heat other than in the light itself; that this is actually effected by nature's processes; and that these are "cheaper," that is, more economical in energy, than any industrial method now known. From the observations and facts given there seems no reason why the light should not one day be produced in the laboratory, and used for industrial purposes.—Contributions to mineralogy, No. 48, by F. A. Genth. Analyses are given of the following minerals: tetradymite, pyrite, quartz (pseudomorphous after stibnite), gold in chromiferous clay from Los Cerillos, New Mexico, zircon, scapolite, garnet, titaniferous garnet, allanite, and lettsomite from Arizona and Utah.—A curious occurrence of vivianite, by Wm. L. Dudley.—Classification of the glacial sediments of Maine, by George H. Stone.—The direct determination of bromine in mixtures of alkaline bromides and iodides, by F. A. Gooch and J. R. Ensign. The method described is as follows: the neutral solution containing the bromide and iodine is diluted to 600 c.c. or 700 c.c., and about 1 c.c. or 1·5 c.c. of strong sulphuric acid, or from 2 c.c. to 3 c.c. of the acid mixed with an equal volume of water, are added; a sufficient amount of sodium or potassium nitrite is then introduced, and the liquid is boiled until the colour has disappeared and the escaping steam no longer gives to red litmus-paper the characteristic colour of iodine. The residual liquid is then treated with excess of silver nitrate, and the precipitated bromide filtered off, dried, and weighed.—Some Lower Silurian graptolites from Northern Maine, by W. W. Dodge.—Siderite-basins of the Hudson River epoch, by James P. Kimball. Some interesting facts bearing on the structural geology of the Taconic area extending to the Hudson River, and on the geology of the whole Taconic region, are brought together and discussed.—On a new variety of zinc sulphide from Cherokee County, Kansas, by James D. Robertson.—Two new meteoric irons, by F. P. Venable. An analysis of a meteorite from Rockingham County, N.C., gave the result: Fe, 87·01; P, 0·04; SiO_2, 0·53; Cl, 0·39; Ni, 11·69; Co, 0·79 = 100·45. Another meteoric iron from Henry County, Vancouver, gave: Fe, 90·54; Cl, 0·35; SiO_2, 0·04; P, 0·13; Co, 0·94; Ni, 7·70 = 99·70.—Notice of some extinct Testudinata, by O. C. Marsh.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 18.—M. Duchartre in the chair.—Contribution to the theory of the experiments of M. Hertz, by M. H. Poincaré. After pointing out an error in the calculations of M. Hertz, an attempt is made, starting with Maxwell's fundamental hypotheses, to develop a more rigorous formula for the rate of propagation of the wave in air.—International meteorological tables, presented by M. Mascart. These are of the form finally decided upon by the International Committee at Zurich, 1888.—Order of appearance of the first vessels in the flowers of some *Tragopogon* and *Scorzonera*, by M. A. Trécul.—Experimental tuberculosis, on a mode of treatment and of vaccination, by MM. J. Grancher and H. Martin. The paper describes the result of some experiments on the inoculation of rabbits. The process described affords a more or less complete protection from tuberculosis to the rabbits inoculated.—On a portable electrical safety-lamp, for use in mines, by M. G. Trouvé. The smallest lamp described, supplied with six Planté accumulators (weight 420 grammes), runs for five hours.—Note on a theorem concerning life annuities, by M. A. Quiquet.—Experiments on transversal magnetization by magnets, by M. C. Decharme.—On an electric lighting-apparatus, for examining the strata in borings, by M. G. Trouvé.—Allyl-cyano-succinic ether; new synthesis by means of cyano-succinic ether, by M. L. Barthe. In this synthesis sodium-cyano-succinic ether is treated in alcoholic solution with allyl iodide. The new ether forms a colourless oil, and distils under 35 mm. pressure at 207°–210°.—Methyl cyano-succinate, and methyl cyano-tri-carballylate, by M. L. Barthe. Both these ethers are produced when sodium-methyl cyanacetate is treated with methyl chloracetate.—Researches on butter and margarine, by M. C. Viollette. This paper contains results of ten complete analyses. By the method given an adulteration of pure butter with ten per cent. of margarine can be detected.—Researches on the optical analysis of butters, by the same. The differences between the values of the refractive indices for pure butter and for margarine are sufficient to serve as the basis of an analytical method.—On a characteristic reaction of cocaine, by M. F. da Silva.

THURSDAY, SEPTEMBER 4, 1890.

THE BRITISH ASSOCIATION.

LEEDS, *Tuesday Evening.*

IT is 32 years since the British Association met at Leeds, this being only its second visit, though it has frequently enough held its meetings in Yorkshire during that period. The President of 1858, Sir Richard Owen, happily still survives, though most of his eminent colleagues of the year have quitted the field—Sir John Herschel, Sir David Brewster, Sir Roderick Murchison Sir Benjamin Brodie, Robert Stephenson, Phillips, Darwin, Nasmyth. But the names of Huxley, Francis Galton, and others then coming into prominence, are found among the list of those who contributed to the proceedings of the meeting. Vast changes have taken place both in Leeds and in science during these 32 years—changes which we need not record here. Leeds during the interval has risen to its present prominence and prosperity mainly through the application of the discoveries of science, and therefore it seems appropriate that this year's President should be one who himself during 30 years has had so much to do with the application of these discoveries. As will be seen, Sir Frederick Abel's address deals largely with his own work in this direction.

So far as can be judged at present, the local authorities have done everything they could to render the meeting a success. All the best buildings in the town have been placed at the disposal of the Association. The Reception Room is spacious and handsome, and, so far as I have seen, the Sectional rooms are all that could be desired. The most thoughtful care has been taken for the comfort and convenience of the visitors. The Sectional Secretaries have seldom been so well housed. Their hotel is just opposite the Reception Room, and not only have well-furnished writing and dining rooms been placed at their disposal, but a handsome billiard room with three tables, on which the Secretaries of Section A hope to work out some abstruse problems. The Guidebook to Leeds, which has been prepared under the editorship of Prof. Miall, is well packed with useful information and guidance, and is handy enough to go into the pocket. A small pamphlet gives full details as to all the arrangements of the meeting, and another all the information about excursions.

As to the general work of the Sections, it is probable that it will be up to the average. So far as I can learn, there is no paper as yet of striking or sensational importance. There will, however, be several discussions that are likely to have useful results. In Section A, for example, there will be a discussion on electrical units, and possibly another on mechanical units and nomenclature. In Section D, again, there will be a discussion on the teaching of botany, in connection with which papers will be read by Dr. F. Oliver, Dr. Scott, and Prof. Marshall Ward, and in which Mr. F. Darwin, Prof. Bower, and others, will take part. A joint meeting will be held, on Monday, of Sections E and F, for the consideration of the important subject of the lands of the globe still available for settlement. One of the most striking papers in Section G will be one by Mr. Read Murphy (a native of Australia), on the Victorian torpedo. The Anthropological Laboratory will be at work this year again, though unfortunately it has been located at a distance from the meeting-room of Section H. Public and private hospitality, it need hardly be said, will be lavish.

INAUGURAL ADDRESS BY SIR FREDERICK AUGUSTUS ABEL, C.B., D.C.L. (OXON.), D.SC. (CANT.), F.R.S., P.P.C.S., HON.M.INST.C.E., PRESIDENT.

MANY who had the pleasure of listening last year, at Newcastle, to the interesting and instructive address of the President to whom I am a most unworthy successor, could not fail, both by the chief subject of his discourse, and by the circumstance of the official position which he occupies with so much benefit to science and the public, to have their thoughts directed to the illustrious naturalist whose philosophical address delighted the members of the Association and the people of Leeds thirty-two years ago.

More than one-half the period of existence of this Association has passed since Richard Owen presided over its meeting in this town. Alas! what gaps have been created in the ranks of those who then were prominent for activity in advancing its work: the then General Secretary, Sir Edward Sabine; the all-popular Assistant-General Secretary, John Phillips; the Treasurer, John Taylor, now live with us only through their works and the enduring esteem which they inspired. But very few of those who held other prominent positions at that meeting have survived to see the Association reassemble in this town. Whewell, Herschel, Hopkins, the elder Brodie, Murchison, William Fairbairn, all Presidents of Sections in 1858, have long since been removed from among us; and the then President of Section F, Edward Baines, a much-honoured and highly-talented son of the "Franklin of Leeds," whom we had hoped to count among those Vice-Presidents representing the city on this occasion, has recently passed away, in his ninetieth year, after a most honourable and useful career, during which he especially distinguished himself by his successful exertions in the advancement of the great educational movements of his time.

The illustrious President of our last meeting here, concerning whose health the gravest apprehensions were not long since entertained, is happily still preserved to us; still intellectually bright at the ripe age of eighty-six, and still, with the keen pleasure of his early life, following the progress of those branches of scientific research which have constituted the favourite occupations and the arena of many intellectual triumphs of a long career of ardent and successful devotion to the advancement of science.

To not a few of those who have flocked to Leeds to attend the annual gathering of this Association, our present meeting-place is doubtless known chiefly by its proud position as one of the most thriving manufacturing towns of the United Kingdom; of ancient renown, especially in connection with one of the chief industries identified with Great Britain in years past. But this good town of Leeds, whose cloth market was described by Daniel Defoe, one hundred and sixty odd years ago, as "a prodigy of its kind, and not to be equalled in the world," and whose present position in connection with divers of our great industries would have equally excited the enthusiasm of that graphic writer, is famous for other things than its prominent association with manufactures and commerce.

Not many of our great industrial centres can boast of so goodly an array, upon the scroll of their past history, of names of men eminent in the Sciences, the Arts and Manufactures, in Divinity and Letters, and in heroic achievements, such as are identified with Leeds and its immediate vicinity: Thomas, Lord Fairfax, one of the most prominent heroes of the Commonwealth; Smeaton, an intellectual giant among engineers; William Hirst and John Marshall, illustrious examples of the men who by their genius, energy, and perseverance placed Great Britain upon the pinnacle of industrial and commercial greatness which she so long occupied unassailed; Richard Bentley, the eminent classic and divine; John Nicholson, the Airedale poet; John Fowler and Peter Fairbairn, worthy followers in the footsteps of Smeaton; Isaac Milner, weaver and mathematician, afterwards Senior Wrangler, Smith's Prizeman, Jacksonian Professor, President of Queen's College, Vice-Chancellor of Cambridge University, Dean of Carlisle, and a

most illustrious Fellow of the Royal Society; Thoresby, antiquarian and topographer; Benjamin Wilson, painter, and industrious contributor to the development of electrical science; William Hey, the eminent surgeon, and friend and counsellor of Priestley; Sadler, political economist and philanthropist; the brothers Sheepshanks—Richard, the astronomer, and John, the accomplished patron of the arts, and munificent contributor to our national art treasures; Edward Baines, whose conspicuous talents and energy developed a small provincial journal into one of the most powerful public organs of the country; his talented sons, of whom not the least conspicuous and highly respected was the late Sir Edward Baines. I might swell this voluminous list by reference to illustrious members of such families as that of Denison, of Beckett, of Lowther, but the men I have referred to fitly illustrate the remarkable array of worthies whose careers have shed lustre upon the town in or near which they were born. Yet that illustration would be altogether incomplete if I failed to speak of one whose career and works alone would suffice to place Leeds in the foremost rank of those English towns which can claim as their own men whose course of life and whose achievements have secured their pre-eminence among our illustrious countrymen. Needless to say that I refer to Joseph Priestley, born within six miles of Leeds, whose name holds rank among the foremost of successful workers in science; who, by brilliant powers of experimental investigation, rapidly achieved a series of discoveries which helped largely to dispel the shroud of mystery surrounding the art of alchemy, and to lay the foundation of true chemical science. An ardent student of the classics, of Eastern languages, and of divinity, a zealous exponent of theological doctrines which marred his career as divine and instructor, he early displayed conspicuous talents for the cultivation of experimental science, which he pursued with ardour under formidable difficulties. His acquaintance with Franklin probably developed the taste for the study of electric science which led him to labour successfully in this direction and the publication, in 1767, of his valuable work on "The History and Present State of Electricity, with Original Experiments," secured for him a prominent position among the working Fellows of the Royal Society. His connection with Mill Hill Chapel, in 1768, appears to have given rise accidentally to his first embracing the experimental pursuit of what formerly was termed pneumatic chemistry, the foundation of which had been laid by Cavendish's memorable contribution, in 1766, to the Philosophical Transactions, on carbonic acid and hydrogen. Priestley's first publication in pneumatic chemistry, on "Impregnating Water with Fixed Air" (carbonic acid), attracted great attention; it was at once translated into French, and the College of Physicians addressed the Lords of the Treasury thereon, pointing out the advantages which might result from the employment, by men at sea, of water impregnated with carbonic acid gas, as a protective against, or cure for, scurvy.

Six years later Priestley investigated the chemical effects produced on the air by the burning of candles and the respiration of animals, and, having demonstrated that it was thereby diminished in volume and deteriorated, he showed that living plants possessed the power of rendering air, which had been thus deteriorated, once more capable of supporting the combustion of a candle. At about this time Priestley received very advantageous proposals to accompany Captain Cook upon his second expedition to the South Seas; but when about to prepare for his departure he learned from Sir Joseph Banks that objections against his appointment, on account of the great latitude of his religious principles, had been successfully urged by some ecclesiastic member of the Board of Longitude. In 1773 the Royal Society awarded Priestley the Copley Medal for a remarkable paper entitled "Observations on Different Kinds of Air," and in that year he became librarian and literary companion to the Earl of Shelburne (afterwards Marquis of Lansdowne), and thereby secured special advantages in the pursuit of his scientific researches.

With respect to his departure from Leeds, he expressed himself as having been very happy there "with a liberal, friendly, and harmonious congregation, to whom my services (of which I was not sparing) were very acceptable. Here I had no unreasonable prejudices to contend with, so that I had full scope for every kind of exertion; and I can truly say that I always considered the office of a Christian minister as the most honourable of any upon earth, and in the studies proper to it I always took the greatest pleasure." During the next five years he published as many volumes describing the results of important experiments on air. After investigating the properties of nitric oxide, and applying it to the analysis of air, Priestley, in 1774, discovered and carefully studied oxygen, which he obtained by the action of heat upon the red oxide of mercury. He was the first to prepare and study sulphurous acid, carbonic oxide, nitrous oxide, hydrochloric acid (*marine acid air*), and the fluoride of silicon, and carried out important researches on the properties of hydrogen, and of other gases previously but little known. His great quickness of perception and power of experiment led him to the achievement of many novel and important results; but one cannot help contrasting his somewhat random search after new discoveries with the close logical reasoning and philosophic spirit which guided and pervaded the remarkable researches of him whose departure from amongst us since the last gathering of this Association is so universally deplored—of the great discoverer of the universal law of the conversion of energy, James Prescott Joule. I could not add to the judicious and graceful reference to his work which Sir Henry Roscoe was privileged to make, in the last year of that philosopher's valuable life, when presiding over the recent meeting of the Association in the town which gloried in numbering Joule among its citizens; but I may, perhaps, be permitted to express the sanguine hope that the desire of the scientific world to secure the establishment of an international memorial fitly commemorative of his great life-work may be realized in the most ample manner.

The wide scope of the admirable discourse delivered by Owen in this town thirty-two years ago affords an interesting illustration of the delight which men whose best energies are devoted to the cultivation of one particular branch of science take in the results of the labours of their fellow-workers in other departments, and in their achievements in contributing to the general advancement of our knowledge of Nature's laws and of their operations. It is to this bond of intimate union between all workers in pure science that we owe the instructive reviews of the progress made in different departments of science, with which we have often been presented at our annual gatherings. On the other hand, those men, from time to time selected to fill the distinguished office of President, whose lives have been mainly devoted to the practical utilization of the results of scientific research, and to the extension in particular directions of the consequent resources of civilization, seize with keen pleasure the opportunity afforded them of directing attention to the triumphs achieved in the application, to the purposes of daily life, of the great scientific truths established by such illustrious labourers in the fields of pure science as Newton, Dalton, Faraday, and Joule. The wide and constantly-extending domain of applied science presents, even to the superficial observer, a continually varied scene; not a year passes but some great prize falls to the lot of one or other of its explorers, and some apparently insignificant vein of treasure, struck upon but a few years back, is rapidly opened out by cunning explorers, until it leads to a mine of vast wealth, from which branch out in many directions new sources of power and might.

Among the branches of science in the practical applications of which the greatest strides have been made since the Association met at Leeds in 1858, is electricity. That year witnessed the accomplishment of the first great step towards the establishment of electrical communication between Europe and America, by the laying of a telegraph-cable connecting Newfoundland with Valencia. Through this cable a message of thirty-one words was shortly afterwards transmitted in thirty-five minutes; an achievement which, though exciting great enthusiasm at the time, scarcely afforded promise of the succession of triumphs of ocean-telegraphy which have since surpassed the wildest dreams of the pioneers in the realms of applied electricity.

The development of the electric telegraph constitutes a never-failing subject of the liveliest interest. The experiments made by Stephen Gray, in 1727, of transmitting electrical impulses through a wire 700 feet long; by Watson, twenty years afterwards, of transmitting frictional electricity through many thousand feet of wire, supported by a line of poles, on Shooter's Hill, in Kent; and by Franklin, who carried out a similar experiment at Philadelphia,—although they were followed by many other interesting and philosophical applications of frictional electricity to the transmission of signals—were not productive of really practical results. The work of Galvani and of Volta was more fruitful of an approach to practical telegraphy in the hands of Sömmering and of Coxe, while the researches of

Oersted, of Ampère, of Sturgeon, and of Ohm, and especially the discoveries of volta-electric induction and magneto-electricity by Faraday, paved the way for the development of the electric telegraph as a practical reality by Cooke and Wheatstone in 1837. How remarkable the strides have been in the resources and powers of the telegraphist since that time is demonstrated by a few such facts as these: the first needle-instrument of Cooke and Wheatstone transmitted messages at the rate of four words per minute, requiring five wires for that purpose; six messages are now conveyed by one wire, at ten times that speed, and news is despatched at the rate of 600 words per minute. Duplex working, which more than doubled the transmitting power of a submarine cable, was soon eclipsed by the application of Edison's quadruplex working, which has in its turn been surpassed by the multiplex system, whereby six messages may be sent independently, in either direction, on one wire. When last the British Association met in Leeds, submarine telegraphy had but just started into existence; thirty years later, the accomplished President of the Mechanical Section informed us, at our meeting at Bath, that 110,000 miles of cable had been laid by British ships, and that a fleet of nearly forty ships was occupied in various oceans in maintaining existing cables and laying new ones.

The important practical achievements by which most formidable difficulties have been surmounted, step by step, in the successive attainment of the marvellous results of our day, have exerted an influence upon the advancement, not merely of electrical science, but also of science generally and of its applications, fully equal to that which they have exercised upon the development of commerce and of the intercourse between the nations of the earth.

Thus, the laying of the earliest submarine cables, between 1851 and 1855, led Sir W. Thomson, in conference with Sir George Stokes, to work out the theory of signalling in such cables, by utilizing the mathematical results arrived at by Fourier in his investigation of the propagation of heat-waves. The failure of the first Atlantic cable led to the survey of the bottom of the Atlantic, which was the forerunner of deep-sea explorations, culminating in the work of the *Challenger* Expedition, and opening up new treasures of knowledge scarcely dreamt of when last the British Association met at Leeds. To the difficulties connected with the early attempts at submarine telegraphy, and the determination with which Thomson drove home the lessons learned, we owe the systematic investigations into the causes of the variations in resistance of copper-conductors, and the consequent improvements in the metallurgy of copper, which led to the realization of the high standard of purity of metal essential for the efficient working of telegraphic systems, and also to the extensive utilization of electricity in the production of pure copper. The rare combination of originality in powers of research and perspicuity in mathematical reasoning, with inventive and constructive genius, for which Thomson has so long been pre-eminent, has placed at the disposal of the investigator of electric science, and of the practical electrician, instruments of measurement and record which have been of incalculable value, and which owe their origin to the theoretical conclusions arrived at by him in his researches into the conditions to be fulfilled for the attainment of practical success in the construction and employment of submarine cables. The mirror galvanometer, the quadrant electrometer, the syphon-recorder, and the divided-ring electrometer, are illustrations of the valuable outcome of Thomson's labours; the combination of the last-named instrument with sliding resistance coils has rendered possible the accurate subdivision of a potential difference into 10,000 equal parts. The general use of condensers in connection with cable signalling, due to Varley's application of them for signalling through submerged cables with induced short waves, was instrumental in establishing the fact that all electro-static phenomena are simply the result of starting an electric current of known short duration round a closed circuit. The practical application of the Wheatstone Bridge led to numerous important mathematical investigations, and induced Clerk Maxwell to devise a new mode of applying determinants to the solution of the complicated electrical problems connected with networks of conductors. The necessity for the universal recognition of an electrical unit of resistance led to the establishment, in 1860, of the Electrical Standards Committee of the British Association, whose long succession of important annual reports was instrumental in most important developments of theoretical electricity, and, indeed, served to open up the whole science of electrical measurement. Matthiessen's important investigations of the electrical behaviour of metals and their alloys, and the preparation and properties of pure iron, were the outcome of the commercial demand for a practically useful standard of electrical resistance; while Latimer Clark's practical standard of electromotive force, the mercurous sulphate cell, became invaluable to the worker in pure electrical research. The unit of resistance established by the British Association Committee received, in 1866, most important scientific application at the hands of Joule, who, by measuring the rate of development of heat in a wire of known resistance by the passage of a known current, obtained a new value of the mechanical equivalent of heat. This value differed by about 1·3 per cent. from the most accurate results arrived at by his experiments on mechanical friction, a difference which eventually proved to be exactly the error in the British Association unit of resistance; so that the true value of the unit of resistance, or Ohm, was determined by Joule fifteen years before this result was achieved by electricians. Clerk Maxwell's remarkable electro-magnetic theory of light was put to the test, through the aid of the British Association unit of resistance, by Thomson, in determining the ratio of the electro-magnetic unit to the electro-static unit of quantity. Many other most interesting illustrations might be given of the invaluable aid afforded to purely scientific research by the practical results of the development of electrical science, and of the constant co-operation between the science student and the practical worker. No one could, more fitly than the late Sir William Siemens, have maintained, as he did in his admirable address at our meeting in Southampton in 1882, that we owe most of the rapid progress of recent times to the man of science who partly devotes his energies to the solution of practical problems, and to the practitioner who finds relaxation in the prosecution of purely scientific inquiries. Most assuredly both these classes of the world's benefactors may with equal right lay claim to rank the name of Siemens among those whom they count most illustrious!

In that highly interesting and valuable address delivered little more than a year before his sudden untimely removal from among us, the numerous important subjects discussed by him included not a few which he had made peculiarly his own in the wide range embraced by his enviable power of combining scientific research with practical work. Prominent among these were the applications of electric energy to lighting and heating purposes, and to the transmission of power, to the future development of which his personal labours very greatly contributed.

Siemens referred to the passing of the first Electric Lighting Bill, in the year of his presidency, as being designed to facilitate the establishment of electric installations in towns; but the anxiety of the Government of that day to protect the interests of the public through local authorities, led to the assignment of such power to these over the property of lighting companies, that the utilization of electric lighting was actually delayed for a time by those legislative measures. There can now be no doubt, however, that this delay has really been in the interests of intending suppliers and of users of the electric light, as having afforded time for the further development of practical details, connected with generation and distribution, which was vital to the attainment of a fair measure of initial success. The subsequent important modification of legislation on the subject of electric lighting, together with the practical realization of comparatively economical methods of distribution, the establishment of fairly equitable arrangements between the public and the lighting companies, and the apportionment, so far as the metropolis is concerned, of distinct areas of operation to different competing companies, have combined to place electric lighting in this country at length upon some approach to a really sound footing, and to give the required impetus to its extensive development. Nine companies either are now, or will very shortly be, actually at work supplying, from central stations, districts of London comprising almost the entire western and north-western portions of the metropolis. As regards other parts of England, there are already twenty-seven lighting stations actually at work in different towns, besides others in course of establishment, and many more projected. The town of Leeds has not failed to give serious attention to the subject of utilizing the electric light, and, although no general scheme has yet been adopted, the electricians who now visit this town will rejoice to see many of its public buildings provided with efficient electric illumination.

While the prediction made by Siemens, eight years ago, that electric lighting must take its place with us as a public illuminant,

has thus been already, in a measure, fulfilled, important progress is being continuously made by the practical electrician in developing and perfecting the arrangements for the generation of the supply, its efficient distribution from centres, and its delivery to the consumer in a form in which it can be safely and conveniently dealt with and applied at an outlay which, even now, does not preclude a considerable section of the public from enjoying the decided advantages presented by electric lighting over illumination by coal-gas. Yet our recent progress in this direction, encouraging though it has been, is insignificant as compared with the strides made in the application of electric lighting in the United States, as may be gauged by the fact that, while in America the number of arc lamps in use, in April of this year, was 235,000, and of glow-lamps about three millions, there are at present only about one-tenth the number of the latter, and one hundredth the number of arc lamps, in operation in England.

In some important directions we may, however, lay claim to rank foremost in the application of the electric light; thus, our large passenger-ships and our war-ships are provided with efficient electrical illumination; to the active operations of our Navy the electric light has become an indispensable adjunct; and our system of coast defence, by artillery and submarine mines, is equally dependent, for its thorough efficiency, upon the applications of electricity in connection with range-finding, with the arrangement and explosion of mines, and with the important auxiliary in attack and defence, the electric light, which, while so arranged, at the operating stations, as to be protected against destruction by artillery-fire and difficult of detection by the enemy, is available at any moment for affording invaluable information and important assistance and protection.

Other important applications of the electric light, such as its use as a lighthouse-illuminant, for the lighting of main roads in coal-mines, where its value is being increasingly appreciated, and even for signalling purposes in mid-air, through the agency of captive balloons, are continually affording fresh demonstrations of the value of this particular branch of applied electric science.

At the Electrical Exhibition at Vienna in 1883, where, not long before the lamented death of Siemens, I had the honour of serving as one of his colleagues in the representation of British interests, the progress which had been made in the construction of electrical measuring instruments since the French Exhibition and the Electrical Congress, two years before, was very considerable. The advance in this direction has been enormous since that time; but although the practical result of Thomson's and of Carlew's important work has been to supply us with trustworthy electrical balances and voltmeters, while efficient instruments have also been made by other well-known practical electricians, we have still to attain results in all respects satisfactory in these indispensable adjuncts to the commercial supply and utilization of electric energy.

In connection with this important subject the recent completion of the Board of Trade standardizing laboratory, established for the purposes of arriving at and maintaining the true values of electrical units, and of securing accuracy and uniformity in the manufacture of instruments supplied by the trade for electrical measurements, may be referred to with much satisfaction as a practical illustration of official recognition of the firm root which the domestic and industrial utilization of electric energy has taken in this country.

The achievements of the telephone were referred to by Siemens in glowing terms eight years ago; but the results then attained were but indications of the direction in which telephonic intercommunication was destined speedily to become one of the most indispensable of present applications of electricity to the purposes of daily life. Preece, in speaking at Bath, two years ago, of the advances made in applied electricity, showed that the impediments to telephonic communication between great distances had been entirely overcome; and now, although considerably behind America and France in the use of the telephone, we are rapidly placing ourselves upon speaking terms with our friends throughout the United Kingdom. The operations of the National Telephone Company well illustrate our progress in telephonic intercommunication: that company has now 22,743 exchange lines, besides nearly 5000 private lines; its exchanges number 272, and its call-offices 526. The number of instruments under rental in England has now reached 99,000; but, important as this figure is compared to our use of the telephone a very few years ago, it sinks into insignificance by the side of the number of instruments under rental in America, which at the beginning of the present year had reached 222,430, being an increase of 16,675 over the number in 1889. Only thirteen years have elapsed since the telephone was first exhibited as a practically workable apparatus to members of the British Association at the Plymouth Meeting, and the number of instruments now at work throughout the world may be estimated as considerably exceeding a million.

The successful transmission of the electric current, and the power of control now exercised over the character which electrically-transmitted energy is made to assume, are not alone illustrated by the efficiency of the arrangements already developed for the supply of the electric light from central stations. Siemens dwelt upon this subject at Southampton with the ardent interest of one who had made its development one of the objects of his energetic labours in later years, and also with a prophet's prognostications of its future importance. In speaking of the electric current as having entered the lists in competition with compressed air, the hydraulic accumulator, and the quick-running rope driven by water-power, Siemens pointed out that no further loss of power was involved in the transformation of electrical into mechanical energy than is due to friction, and to the heating of the conducting wires by the resistance they oppose, and he showed that this loss, calculated upon data arrived at by Dr. John Hopkinson and by himself, amounted at the outside to 38 per cent. of the total energy. Subsequent careful researches by the Brothers Hopkinson have demonstrated that the actual loss is now much less than it was computed at in 1885; as much as 87 per cent. of the total energy transmitted being realizable at a distance, provided there be no loss in the connecting leads used.

The Paris Electric Exhibition of 1881 already afforded interesting illustrations of the performance of a variety of work by power electrically transmitted, including a short line of railway constructed by the firm of Siemens, which was a further development of the successful result already attained in Berlin by Werner Siemens in the same direction, and was, in its turn, surpassed by the considerably longer line worked by Messrs. Siemens at the Vienna Exhibition two years later. Various short lines which have since then been established by the firm of Siemens are well known, and one of the latest public acts in the valuable life of Siemens was to assist at the opening of the electric tramway at Portrush, in the installation of which he took an active part, and where the idea, so firmly rooted in his mind from the date of his visit to the Falls of Niagara, in 1876, of utilizing water-power for electrical transmission—a result first achieved on a small scale by Lord Armstrong—was more practically realized than had yet been the case. Since that time Ireland has witnessed a further application of electricity to traction purposes, and of water-power to the provision of the required energy, in the working of the Bessbrook and Newry tramway, while London at length possesses an electric railway, three miles in length, to be very shortly opened, which will connect the City with one of the southern suburbs through a tram subway, and, although including many sharp curves and steep gradients, will be capable of conveying one hundred passengers at a time, at speeds varying from thirteen to twenty-four miles per hour. During the past year a regular service of tramcars has been successfully worked, through the agency of secondary batteries, upon part of one of the large tramways of North London, with results which bid fair to lead to an extensive development of this system of working. The application of electricity to traction purposes has, however, received far more important development in the United States; at the commencement of this year there were in operation in different States 200 electrical tramroads, chiefly worked upon the Thomson-Houston and the Sprague systems, and having a collective length of 1641 miles, with 2346 motor-cars travelling thereon. Further extensions are being rapidly made; thus, one company alone has 39 additional roads, of a collective length of 385 miles, under construction, to be worked through the agency of storage-batteries.

The idea cherished by Siemens, and enlarged upon by him in more than one interesting address, of utilizing the power of Niagara, appears about to be realized, at any rate in part; as a large tract of land has been recently acquired, by a powerful American association, about a mile distant from the Falls, with a view to the erection of mills for utilizing the power, which it is also proposed to transmit to distant towns; and an International Commission, with Sir William Thomson at its head, and with Mascart, Turrettini, Coleman Sellers, and Unwin as members, will carefully consider the problems involved in the execution of this grand scheme.

The application of electric traction to water-traffic, first successfully demonstrated in 1883, is receiving gradual development, as illustrated by the considerable number of pleasure-boats which may now be seen on the Upper Thames during the boating season, and in connection with which Prof. George Forbes proposed, at our meeting last year, that stations for charging the requisite cells, through the agency of water-power, should be established at the many weirs along the river, so as to provide convenient electric coaling-stations for the river pleasure-fleet.

Electrically-transmitted energy was first applied in Germany to haulage work in mines by the firm of Siemens some years ago, and great progress has since been achieved herein on the Continent and in America. Comparatively little has been accomplished in this direction in England; but it is very interesting to note, on the present occasion, that the first successful practical application of electricity in this country to pumping and underground haulage-work was made in 1887, in this neighbourhood, at the St. John's Colliery, at Normanton, where an extensive installation, carried out by Mr. Immisch, so well known in connection with electric launches, is furnishing very satisfactory results in point of economy and efficiency. The gigantic installations existing for the same purposes in Nevada and California afford remarkable illustrations of the work to be accomplished in the future by electrically-transmitted energy.

Among the many subjects of importance studied by Joule with the originality and thoroughness characteristic of his work, was the application of voltaic electricity to the welding and fusion of metals. Thirty-four years ago he published a most suggestive paper on the subject, in which, after dealing with the difficulties attending the operation of welding, and of the interference of films of oxide, formed upon the highly heated iron surfaces, with the production of perfect welds either under the hammer or by the methods of pressure (of which he then predicted the application to large masses of forged iron), he refers to the possibility of applying the calorific agency of the electric current to the welding of metals, and describes an operation witnessed by him in the laboratory of his fellow-labourer, Thomson, of fusing together a bundle of iron wires by transmitting through them, when embedded in charcoal, a powerful voltaic current. Joule afterwards succeeded in fusing together a number of iron wires with the current of a Daniell battery, and in welding together wires of brass and steel, platinum and iron, &c. In discussing the question of the amount of zinc consumed in a battery for raising a given amount of iron to the temperature of fusion, he points out that the same object would probably be more economically attained by the use of a magneto-electric machine, which would allow the heat to be provided by the expenditure of mechanical force, developed in the first instance by the expenditure of heat; and he indicates the possibility of arranging machinery to produce electric currents which shall evolve one-tenth of the total heat due to the combustion of the coal used, so that 5000 grains of coal applied through that agency would suffice for the fusion of one pound of iron. The successful practical realization of Joule's predictions in regard to the application of electric currents, thus developed, to the welding of iron and steel, and to analogous operations, through the agency of the efficient machines devised by Prof. Elihu Thomson, was demonstrated to the members of the Association by Prof. Ayrton at Bath two years ago, and was shown upon a larger scale to visitors at the Paris Exhibition last year, and recently to highly interested audiences in London by our late President, Sir Frederick Bramwell. The latter demonstrated that the production of iron-welds by means of the Thomson machines was accomplished nearly twice as rapidly as by expert craftsmen; the perfection of the welds being proved by the fact that the strength of bars broken by tensile strains at the welds themselves was about 92 per cent. of the strength of the solid metal. At the Crewe Works Mr. Webb is successfully applying one of these machines to a variety of welding-work. The rapidity with which masses of metal of various dimensions are raised in those machines to welding heat is quite under control; the heat is applied without the advent of any impurities, as from fuel, and the speed of execution of the welding operation reduces to a minimum the time during which the heated surfaces are liable to oxidize. With such practical advantages as these, this system of electric welding bids fair to receive many useful applications.

Another very simple system of electric welding, especially applicable to thin iron and steel sheets, hoops, &c., has been cotemporaneously elaborated in Russia by Dr. Bernados, and is already being extensively used. The required heat at the surfaces to be welded is developed by connecting the metal with the negative pole of the dynamo-machine, or a battery of accumulators, the circuit being completed by applying a carbon electrode to the parts to be heated; the reducing power of the carbon is said to preserve the heated metal surfaces from oxidation during the very brief period of heating. This mode of operation appears to have been practised upon a small scale, some years ago, by Sir William Siemens, to whom we also owe the first attempt to practically apply electric energy to the smelting of metals.

In his address in 1882 he referred to some results attained with his small electrical furnace, and pointed out that, although electric energy could, obviously, not compete economically with the direct combustion of fuel for the production of ordinary degrees of heat, the electric furnace would probably receive advantageous application for the attainment of temperatures exceeding the limits (about 1800° C.) beyond which combustion was known to proceed very sluggishly. This prediction appears to have been already realized through the important labours of Messrs. Cowles, who some years ago attacked the subject of the application of electricity to the achievement of metallurgic operations with the characteristic vigour and fertility of resource of our Transatlantic brethren. After very promising preliminary experiments, they succeeded, in 1885, at Cleveland, Ohio, in maturing a method of operation for the production of aluminium-bronze, ferro-aluminium, and silicium-bronze, with results so satisfactory as to lead to the erection of extensive works at Lockport, N.Y., where three dynamo-machines, each supplying a current of about 3000 Amperes, are worked by water-power, through the agency of turbines, each of 500 horse-power, eighteen electric furnaces being now in operation for the production of aluminium alloys. These achievements have led to the establishment of similar works in North Staffordshire, where a gigantic dynamo-machine has been erected, furnishing a current of 5000 Amperes, with an E.M.F. of 50 to 60 volts. The arrangements of the electrodes in the furnaces, the preparation of the furnace-charges (consisting of mixtures of aluminium-ore with charcoal and with the particular granulated metal with which the aluminium is to become alloyed at the moment of its elimination from the ore); the appliances for securing safety in dealing with the current from the huge dynamo-machine, and many other details connected with this new system of metallurgic work, possess great interest. Various valuable copper- and aluminium-alloys are now produced by alloying copper itself with definite proportions of the copper-alloy, very rich in aluminium, which is the product of the electric furnace. The rapid production in large quantities of ferro-aluminium—which presents the aluminium in a form suitable for addition in definite proportions to fluid cast-iron and steel—is another useful outcome of the practical development of the electric furnace by Messrs. Cowles.

The electric process of producing aluminium-alloys has, however, to compete commercially with their manufacture by adding to metals, or alloys, pure aluminium produced by processes based upon the method originally indicated by Oersted in 1824, successfully carried out by Wöhler three years later, and developed into a practical process by H. Ste. Claire Deville in 1854—namely, by eliminating aluminium from the double chloride of sodium and aluminium in the presence of a fluoride, through the agency of sodium. An analogous process, indicated in the first instance by H. Rose—namely, the corresponding action of sodium upon the mineral cryolite, a double fluoride of aluminium and sodium—has also been recently developed at Newcastle, where the first of these methods was applied, upon a somewhat considerable scale, in 1860, by Sir Lowthian Bell, but did not then become a commercial success, mainly owing to the costliness of the requisite sodium. As the cost of this metal chiefly determines the price of the aluminium, technical chemists have devoted their best energies to the perfection and simplification of methods for its production, and the success which has culminated in the admirable Castner process constitutes one of the most interesting of recent illustrations of the progress made in technical chemistry, consequent upon the happy blending of chemical with mechanical science, through the labours of the chemical engineer.

Those who, like myself, remember how, between forty and fifty years ago, a few grains of sodium and potassium were treasured up by the chemist, and used with parsimonious care in an occasional lecture-experiment, cannot tire of feasting their eyes on the stores of sodium-ingots to be seen at Oldbury as the

results of a rapidly and dexterously executed series of chemical and mechanical operations.

The reduction which has been effected in the cost of production of aluminium through this and other processes, and which has certainly not yet reached its limit, can scarcely fail to lead to applications of the valuable chemical and physical properties of this metal so widespread as to render it as indispensable in industries and the purposes of daily life as those well-known metals which may be termed domestic, even although, and, indeed, for the very reason that, its association with many of these, in small proportion only, may suffice to enhance their valuable properties or to impart to them novel characteristics.

The Swedish metallurgist, Wittenström, appears to have been the first to observe that the addition of small quantities of aluminium to fused steel and malleable iron had the effect of rendering them more fluid, and, by thus facilitating the escape of entangled gases, of ensuring the production of sound castings without any prejudicial effect upon the quality of the metal. The excellence of the so-called Mitis castings, produced in this way, appears thoroughly established, and the results of recent important experiments seem to be opening up a field for the extensive employment of aluminium in this direction, provided its cost becomes sufficiently reduced. The valuable scientific and practical experiments of W. J. Keep, James Riley, R. Hadfield, Stead, and other talented workers in this country and the United States, are rapidly extending our knowledge in regard to the real effects of aluminium upon steel, and their causes. Thus it appears to be already established that the modifications in some of the physical properties of steel resulting from the addition of that metal, are not merely ascribable to its actual entrance into the composition of the steel, but are due, in part, to the de-oxidation by aluminium of some proportion of iron-oxide which exists distributed through the metal, and prejudicially affects its fluidity when melted. In the latter respect, therefore, the influence exerted by aluminium, when introduced in small proportions into malleable iron and steel, appears to be quite analogous to that of phosphorus, silicium, or lead when these are added in small proportions to copper and certain of its alloys, the de-oxidation of which, through the agency of those substances, results in the production of sound castings of increased strength and uniformity. It is only when present in small proportion in the finished steel that aluminium increases the breaking strain and elastic limit of the product.

The influence of aluminium, when used in small proportion, upon the properties of grey and white cast-iron, is also of considerable interest, especially its effect in promoting the production of sound castings, and of modifying the character of white iron in a similar manner to silicium, causing the carbon to be separated in the graphitic form; with this difference—that the carbon appears to be held in solution until the moment of setting of the liquid metal, when it is instantaneously liberated, with the result that the structure of the cast metal and distribution of the graphite are perfectly uniform throughout.

The probable beneficial connection of aluminium with the industries of iron and steel naturally directs attention to the great practical importance, in the same direction, which has already been acquired, and promises to be in increasing measure attained, by certain other metals which, for long periods succeeding their discovery, have either been only of purely scientific interest and importance, or have acquired practical value in regard to their positions in a few directions quite unconnected with metallurgy. Thus great interest attaches to the influence of the metals manganese, chromium, and tungsten upon the physical properties of steel and iron.

The name of Mushet is most prominently associated with the history of manganese in its relations to iron and steel. Half a century ago David Mushet carried out very instructive experiments on the influence exerted upon the properties of steel by the presence of manganese; and to Robert Mushet we owe the invaluable experiments leading to his suggestion to use manganese in the production of steel by the Bessemer process, which at once smoothed the path to the marvellously rapid and extensive development of the applications of steel produced by that classic method, and subsequently by the open-hearth or Siemens-Martin process—a development which has recently received its crowning illustration in the completion of one of the grandest of existing triumphs of engineering science and constructive skill—the Forth Bridge.

Robert Hadfield has recently contributed importantly to our knowledge of the relations of manganese to iron. His systematic study of the subject has revealed some very remarkable variations in the physical properties of so-called manganese-steel, according to the proportions of manganese which it contains. Thus, while the existence in steel of proportions ranging from 0·1 up to about 2·75 per cent. improves its strength and malleability, it becomes brittle if that limit is exceeded, the extreme of brittleness being obtained with between 4 and 5 per cent. of manganese; if, however, the percentage is increased to not less than 7, and up to 20, alloys of remarkable strength and toughness are obtained. Castings of high manganese steel, such as wheel-tyres, combine remarkable hardness with toughness. Even if the proportion of manganese is as high as 20 per cent. in a steel containing 2 per cent. of carbon, it can be forged; whereas it is very difficult to forge a steel of ordinary composition containing as much as 2·75 per cent. of carbon. Another remarkable peculiarity of the high manganese-steel is its behaviour when quenched in water. Instead of the heated metal being hardened and rendered brittle by the sudden cooling, like carbon-steel, its tensile strength and its toughness are increased; so that water-quenching is really a toughening process, as applied to the manganese-alloy; and an interesting feature connected with this is that, the colder the bath into which the highly-heated metal is plunged, the tougher is the product. The curious effect of manganese in reducing, and even destroying, the magnetic properties of iron was already noticed by Rinmann nearly 120 years ago; one result of Hadfield's important labours has been to place in the hands of such eminent physicists as Thomson, John Hopkinson, and Reinold, materials for the attainment of most interesting information respecting the electrical and other physical characteristics of manganese-steel. Hopkinson, from experiments with a sample of steel containing 12 per cent. of manganese, estimated that not more than 5 out of the 86 per cent. of the iron composing the mass was magnetic, and he considered that the manganese enters into that which must, for magnetic purposes, be regarded as the molecule of iron, completely changing its properties, a fact which must have great significance in any theory regarding the nature of magnetization. The great hardness of manganese-steel, and the consequent difficulty of dealing with it by means of cutting-tools, constitute at present the chief impediments to its technical applications in many directions; but where great accuracy of dimensions is not required, and where great strength is an essential, it is already put to valuable uses.

The importance of manganese in connection with the metallurgy of iron and steel is in a fair way of finding its rival in that of the metal chromium, the employment of which, as an alloy with steel, was first made the subject of experiment in 1821, by Berthier, who was led by the important experiments of Faraday and Stoddart, then just published, to endeavour to alloy chromium with steel, and obtained good results by fusing steel together with a rich alloy of chromium and iron, so as to introduce about 15 per cent. of the former into the metal. Further small experiments were made the year following, by Faraday and Stoddart, in the same direction; but chrome-steel appears to have been first produced commercially at Brooklyn, N.Y., sixteen years ago. Ten years later its manufacture had become developed in France, and the varieties of chrome-steel produced in the Loire district now receive important and continually-extending applications, on account of their combining comparative hardness with high tenacity, and only little loss in ductility, and of their acquiring great closeness of structure when tempered.

The influence of chromium upon the character of steel differs in several marked respects from that exercised by manganese; thus, chrome-steels weld badly, or not at all, whereas manganese-steels weld very readily, and work under the hammer better than ordinary carbon-steel. Again, the remarkable influence of manganese upon the magnetic properties of steel and iron is not shared by chromium. Chrome-steel has for some time been a formidable rival of the very highest qualities of carbon-steel produced for cutting-tools, and of the valuable tungsten-steel which we owe to Robert Mushet. The great hardness, high tenacity, and exceeding closeness of structure possessed by suitably-tempered steel containing not more than from 1 to 1·5 per cent. of chromium, and from 0·8 to 1 per cent. of carbon, renders this material invaluable for war purposes: cast projectiles, when suitably tempered, have penetrated compound steel and iron plates over nine inches in thickness, such as are used upon armoured ships of war, without even sustaining any important change of form. The proper tempering of these

projectiles necessitates their being produced hollow; their cavities or chambers are only of small capacity, but the charge of violent explosive which they can contain, and which can be set into action without the intervention of fuze or detonating appliance, suffices to tear these formidable punching-tools into fragments as they force their way irresistibly through the armoured side of a ship, and to violently project those fragments in all directions, with fearfully destructive effects. The employment of chromium as a constituent of steel plates used for the protection of ships of war is already being entered upon, and the influence exerted by the presence of that metal in small quantities in steel employed in the construction of guns is also at present a subject of investigation. At Crewe, Mr. F. Webb has for some time past used chromium, with considerable advantage, in the production of high-quality steels for railway requirements.

The practical results attained by the introduction of copper and of nickel as components of steel have also recently attracted much attention. At the celebrated French steel works of M. Schneider, at Creuzot, the addition of a small percentage of copper to steel used for armour-plates and projectiles is practised, with the object of imparting hardness to the metal without prejudice to its toughness. James Riley has found that the presence of aluminium in very small quantities facilitates the union of steel with a small proportion of copper, and that the latter increases the strength but does not improve the working qualities of steel. With nickel, Riley has obtained products analogous in many important respects to manganese steel; the remarkable differences in the physical properties of the manganese alloys, according to their richness in that metal, are also shared by the nickel alloys, some of these being possessed of very valuable properties; thus, it has been shown by Riley that a particular variety of nickel-steel presents to the engineer the means of nearly doubling boiler-pressures, without increasing weight or dimensions. He has, moreover, found the co-existence of manganese in small quantity with nickel in the alloy to contribute importantly to the development of valuable physical properties.

The careful study of the alloys of aluminium, chromium, manganese, tungsten, copper, and nickel, with iron and with steel, so far as it has been carried, with especial reference to the influence which they respectively exercise upon the salient physical properties of those materials, even when present in them in only very small proportions, has demonstrated the importance of a more searching or complete application of chemical analysis, than hitherto practised, to the determination of the composition of the varieties of steel which practical experience has shown to be peculiarly adapted to particular uses. It appears, indeed, not improbable that certain properties of these, which have been ascribed to slight variations in the proportion or the condition of the constituent carbon, or in the amounts of silicium, phosphorus, and manganese which they contain, may sometimes have been due to the presence in minute quantities of one or other of such metals as those named, and to the effects which they produce, either directly, or indirectly by modifying or counteracting the effects of the normal constituents of steel. The important part now played by manganese in steel manufacture is an illustration of the comparatively recent results of research, and of practical work based on research, in these directions, and the effects of the presence in steel of only very small quantities of some of the other metals named are already, as I have pointed out, being similarly understood and utilized.

Such systematic researches as those upon which Osmond, Roberts-Austen, and many other workers have been for some time past engaged, may make us acquainted with the laws which govern the modifications effected in the physical characteristics of metals by alloying these with small proportions of other metals. The suggestion of Roberts-Austen, that such modifications may have direct connection with the periodic law of Mendeleeff, which may furnish explanations of the causes of specific variations in the properties of iron and steel, has been followed up energetically by Osmond, who has experimentally investigated the thermal influence upon iron of the elements phosphorus, sulphur, arsenic, boron, silicium, nickel, manganese, chromium, copper, and tungsten. He regards his results as being quite confirmatory of the soundness of Roberts-Austen's suggestion, as they demonstrate that foreign elements having atomic volumes lower than iron tend to make it assume or preserve the particular molecular form in which it has itself the lowest atomic volume, while the converse is the case for the foreign elements of high atomic volume. An analogous influence was found to be exerted by those two groups of elements upon the permanent magnetization of steel.

Captivating as such deductions are, those who have devoted much attention to the practical investigation of iron, steel, and other metals, cannot but feel that much caution has to be exercised in drawing broad conclusions from the results of such researches as these. Like the investigations recently made with the object of ascertaining the condition in which carbon exists in steel, and the part played by it in determining the modifications in the properties developed in that material by the influence of temperature and of work done upon it, they are surrounded by formidable difficulties, arising from the practical impossibility of altogether eliminating the disturbing influences of minute quantities of foreign elementary bodies, co-existing in the metal operated upon, with those whose effects we desire to study. Certain it is, however, that by acquiring an accurate acquaintance with the composition of varieties of iron and steel exhibiting characteristic properties; by persevering in the all-important work of systematic practical examination of the mechanical and physical peculiarities developed in iron and steel of known composition by their association with one or more of the rarer metals in varied proportions, and by the further prosecution of chemical and physical research in such directions as those which have already been fruitful of most instructive results, such talented labourers as Chernoff, Osmond, Roberts-Austen, Barus and Strouhal, Hadfield, Keep, James Riley, Stead, Turner, and others, cannot fail to contribute continually to the development of improvements equalling in importance those already attained in the production, treatment, and methods of applying cast-iron, malleable iron, and steel, or alloys equivalent to steel in their qualities.

The causes of the variations in the physical properties of steel produced by the so-called hardening, annealing, and tempering processes were for very many years a fruitful subject of experimental inquiry, as well as of theoretical speculation with regard to the condition in which the carbon is distributed in steel, according to whether the metal is hardened or annealed, or in an intermediate, tempered state. Recent researches have made our knowledge in the latter direction fairly precise; as yet, however, we are only on the track of definite information respecting the nature and extent of connection between the physical peculiarities of steel in those different conditions and the established differences in the form and manner in which the carbon is disseminated through it.

The careful systematic study of the modifications developed in certain physical properties of iron and steel by gradual changes of temperature between fusion of the metal and the normal temperature, has shown those modifications to be governed by a constant law, and that at certain critical temperatures special phenomena present themselves. This important subject, which was so clearly brought before the Association last year in the interesting lecture of Roberts-Austen, has been, and is still being pursued by accomplished workers, among whom the most prominent is F. Osmond. The phenomenon of recalescence, or the re-glowing of, or liberation of heat in, iron and steel at certain stages during the cooling process, first noticed by Gore, and examined into by Barrett, appears to be the result of actual chemical combination between the metal and its contained carbon at the particular temperature attained at the time; while the absorption of heat, demonstrated by the arrest in rise of temperature during its continuous application to the metal, is ascribed to the elimination, within the mass, of carbon as an iron-carbide perfectly stable at low temperatures. The pursuit of a well-devised system of experimental inquiry into this subject has led Osmond to propound theories of the hardening and tempering of steel, which are at present receiving the careful study of physicists and chemists, and cannot fail to lead to further important advancement of our knowledge of the true nature of the influence of carbon upon the properties of iron.

Another important subject connected with the treatment of masses of steel, and with the influence exercised upon their physical characteristics by the processes of hardening and tempering, and by submitting them to oft-repeated concussions or vibrations, or frequent or long-continued strains, is the development and maintenance, or gradual disappearance, of internal stresses in the masses—one of the many important subjects to which attention was directed by Dr. Anderson, the Director-General of Ordnance Factories, in his very suggestive address to the Mechanical Section last year. This question is one of

especial interest to the constructor of steel guns, as the powers of endurance of these do not simply depend upon the quality of the material composing them, but are very largely influenced by the treatment which it receives at the hands of the gun-maker. Indeed, the highest importance attaches to the processes which are applied to the preliminary preparation of the individual parts of which the gun is constructed, and to the putting together of these so as to ensure their being and remaining in the physical condition best calculated to assist each other in securing for the structure the power of so successfully resisting the heavy strains to which it has to be subjected, as to suffer little alteration other than that due to the superficial action of the highly-heated products of explosion of the charges fired in the gun. The development of internal strains in objects of steel, especially by the hardening and tempering processes, or by their exposure to conditions favourable to unequal cooling of different parts of the mass, has long been a subject of much trouble and of experimental inquiry in connection with many applications of steel. Systematic experiments of the kind, commenced, about eighteen years ago, by the late Russian general Kalakoutsky, are now being pursued at Woolwich, with the objects of determining the nature and causes of internal stresses in steel gun-hoops and -tubes, and in shells, and of thereby establishing the proper course to be adopted for avoiding, lessening, or counteracting injurious stresses, on the one hand, and for setting up stresses beneficial to the powers of endurance of guns, on the other. One method of experiment pursued, with parts of guns, is to cut narrow hoops off the forgings, after a particular treatment, which are then cut right across at one place, it being observed whether, and to what extent, the resulting gaps open or close. This important subject has also been similarly investigated by my talented old friend and fellow-worker, the President this year of the Mechanical Section, Captain Andrew Noble, whose name in connection with the science and practice of artillery is familiar to us as household words.

The Crimean War taught nations many lessons of gravest import, to some of which Sir Richard Owen took occasion to call attention most impressively in the address delivered here, before the miseries of that war had become past history. The development of sanitary science, to which he especially referred, and which sprang from the bitter experience of that sad epoch, has had its parallel in the development of the science of artillery; but it would indeed be difficult to establish any parallelism between the benefits which even the soldier and the sailor have reaped from the great strides made by both these sciences. The acquisition of knowledge of the causes of the then hopelessness of gallant struggles which medical skill and self-sacrificing devotion made against the sufferings of the victims of battles and of fell diseases, as deadly as the cruellest implements of war; the application of that knowledge to the provision of the blessings of antiseptic treatment of wounds and to the intelligent utilization of disinfectants and of other valuable preventive measures, to the supply of wholesome water, of wholesome food in campaigning, of sensible clothing, and of wholesome air in hospitals, barracks, and ships—these are some few of the benefits which the soldier and the sailor have derived from the development of sanitary science, which was so powerfully stimulated by the terrible lessons learned during the long-drawn-out siege of Sebastopol: and it is indeed pleasant to reflect that there has been, for years past, most wholesome competition between nations in the enlargement of those benefits, and their dissemination among the men whose vocation it is to slay and be slain. The periodical International Congresses on Hygiene and Demography, of which we shall cordially welcome next year's assemblage in London, and whose members will deplore the absence from among them of the veteran Nestor in the science and practice of hygiene, Sir Edwin Chadwick, have afforded conclusive demonstration of the heartiness with which nations are now co-operating with a view to utilize the invaluable results attained by the successful labourers in sanitary science.

What, on the other hand, shall we say of the benefits which sailors and soldiers, in the pursuit of their calling, derive from the ceaseless costly competition amongst nations for supremacy in the possession of formidable artillery, violent explosives, quick-firing arms of deadly accuracy, and fearful engines which, unseen, can work wholesale destruction in a fleet? And what can we say of the benefits acquired by individual countries in return for their continuous, and sometimes ruinous, expenditure in endeavouring to maintain themselves upon an equality with their neighbours in man-killing power? The conditions under which engagements by sea or land will in the future be fought have certainly become greatly modified from those of thirty-five years ago, and the duration of warfare, even between nations in conflict who are on a fair equality of resources, must become reduced; but, as regards the results of a trial of strength between contending forces, similarly equipped, as they now will be, with the latest of modern appliances only varying in detail, these must, after all, depend, as of old, partly upon accident, favoured, perhaps, by a temporary superiority in equipment, partly upon the skill and military genius of individuals, and very much upon the characteristics of the men who fight the battles.

What really can be said in favour of the advances made in the appliances of war—and this is, perhaps, the view which in such a town as Leeds we should keep before our eyes to the exclusion of the dark side of the picture—is, that by continuous competition in the development of their magnitude, diversity, and perfection, the resources of the manufacturer, the chemist, the engineer, the electrician, are taxed to the uttermost; with the very important, although incidental, results, that industries are created or expanded and perfected, trades maintained and developed, and new achievements accomplished in applied science, which in time beneficially affect the advance of peaceful arts and manufactures. In these ways the expenditure of a large proportion of a country's resources upon material which is destroyed in creating destruction does substantially benefit communities, and tends to the accomplishment of such material progress by a country as goes far to compensate its people for the sacrifices which they are called upon to incur for the maintenance of their dignity among nations.

From this point of view, at any rate, it may interest members of the British Association for the Advancement of Science, and for the promotion of its applications to the welfare and happiness of mankind, to hear something of recent advances in one of the several branches of science in its applications to naval and military requirements with which, during a long and arduous official career, now approaching its close, I have become in some measure identified.

Since the meeting of the Association in this town in 1858, the progress which has been made in the regulation of the explosive force of gunpowder, so as to adapt it to the safe development of very high energy in guns presenting great differences in regard to size and to the work which they have to perform, has been most important. The different forms of gunpowder which were applied to war-purposes in this and other countries, until within the last few years, presented comparatively few differences in composition and methods of manufacture from each other, and from the gunpowder of our ancestors. The replacement of smooth-bore guns by rifled artillery, which followed the Crimean War, and the great increase in the size and power of guns, necessitated by the application of armour to ships and forts, soon called, however, for the pursuit of investigations having for their object the attainment of means for variously modifying the action of fired gunpowder, so as to render it suitable for artillery of different calibres whose power could not be effectively, or, in some instances, safely, developed by the use of the only kind of gunpowder then employed in English artillery of all calibres.

The means resorted to in the earlier of these investigations, and adhered to for many years, for controlling the violence of explosion of gunpowder, consisted exclusively in modifying the size and form of the individual masses composing a charge, and of their density and hardness, with the object of varying the rate of burning of those masses in a gun; it being considered that, as the proportions of ingredients generally employed very nearly correspond to those required for the development of the greatest chemical energy by the thoroughly-incorporated materials, the attainment of the desired results should be, if possible, effected rather by modifications of the physical and mechanical characters of gunpowder, than by variations of the proportions and chemical characters of its ingredients.

The varieties of powder from time to time introduced into artillery-service, as the outcome of investigations in this direction, were of two distinct types: the first of these consisted of further developments of the old granulated or corned powder, being produced by breaking up more or less highly-pressed slabs of the material into grains, pebbles, or boulders of approximately uniform size and shape. Gunpowders of this class, ranging in size from about 1000 pieces to the ounce to about 6 pieces to the pound, have performed efficient service, and certain of them are still employed. The character of the other type is based upon the theoretical view that uniformity in the action of a

particular gunpowder, when employed under like conditions, demands not merely identity in regard to composition, but also identity in form, size, density, and structure of the individual masses of which a charge consists. To approach the practical realization of this view, equal quantities of one and the same mixture of ingredients, presented in the form of powder of uniform fineness and dryness, must be submitted to a particular pressure, for a fixed period, in moulds of uniform size, the surrounding conditions and subsequent manufacturing processes being as nearly as possible alike. Practical experience has however shown that uniformity in the ballistic properties of black powder can be even more readily secured by the thorough blending or mixing together of different products of manufacture, presenting some variations in regard to size, density, hardness, or other features, than by aiming at an approach to identity in the characters of the individual grains or masses.

When our attention was first actively directed to the modification of the ballistic properties of powder, the subject had already been to some extent dealt with, in the United States, by Rodman and Doremus, and the latter had proposed the employment, in heavy guns, of charges consisting of large pellets of prismatic form. While this prismatic powder, which was first used in Russia, was being perfected, and extensively applied there as well as in Germany and England, the production of powder-masses more suitable, by the comparatively gradual nature of their explosion, for the very large charges required for the heavy artillery of the present day, was actively pursued in Italy, and by our own Government Committee on Explosives; the outcome of exhaustive practical investigations being the very efficient Fossano powder, or *poudre progressif* of the Italians, and the boulder- and large cylindrical-powders produced at Waltham Abbey.

Researches carried out by Captain Noble and myself, some years ago, with a series of gunpowders, presenting considerable differences in composition, indicated that decided advantages might be secured, for heavy guns especially, by the employment of such a powder as would furnish a comparatively very large volume of gas, its explosion being at the same time attended by the development of much less heat than in the case of ordinary black powder. In the course of these researches much light was thrown upon the causes of the wearing or erosive action of powder-explosions upon the inner surface of the gun, an action which, especially in the larger calibres of artillery, produces so serious a deterioration of the arm that the velocity of projection and accuracy of shooting suffer considerably, the wear being especially great where the products of explosion, while under the maximum pressure, can escape between the projectile and the bore. The great velocity with which the very highly-heated gaseous and liquid (fused solid) products of explosion sweep over the heated surface of the metal gives rise to a displacement of the particles composing the surface of the bore, which increases in extent as the latter becomes roughened, and thus opposes greater resistance; at the same time, the high temperature to which the surface is raised reduces the rigidity of the metal, and its consequent power of resisting the force of the gaseous torrent; and, lastly, some amount of chemical action upon the metal, by certain of the highly-heated, non-gaseous products of explosion, contributes towards an increase in the erosive effects. Experiments made upon a large scale by Captain Noble with powders of different composition, and with other explosives, have afforded decisive evidence that the explosive agent which furnishes the largest proportion of gaseous products, and the explosion of which is attended by the development of the smallest amount of heat, exerts least erosive action.

Some eminent German gunpowder-manufacturers, who were at this time actively engaged upon the production of a suitable powder for heavy guns, directed their attention, not merely to an alteration of the proportions of the ingredients, but also to a modification in the character of charcoal employed; the eventual result was the production of a new prismatic powder, composed of saltpetre in somewhat higher proportion than in normal black powder, and of a very slightly-burned charcoal of reddish-brown colour, quite similar to the *charbon roux* which Violette produced about forty years ago for use in sporting-powder, by the action of superheated steam upon wood or other vegetable matter. This brown prismatic powder (or "cocoa powder") differs from black powder not merely in colour: it burns very slowly in the open air, and in guns its action is comparatively gradual and long-sustained. The products of its explosion are simple. As the powder contains saltpetre in large proportion relatively to the sulphur and charcoal, these become fully oxidized, and a relatively very large amount of water-vapour is produced, partly because of the comparatively high proportion of water in the finished powder, and partly from the large amount of hydrogen in the slightly-charred wood or straw used. The smoke from a charge of brown powder differs but little in volume from that of black powder, but it disperses much more rapidly, owing to the speedy absorption of the finely-divided potassium salts, forming the smoke, by the large proportion of water-vapour through which they are distributed.

This kind of powder has been substituted, with considerable advantage, for black powder in guns of comparatively large calibre, but it soon became desirable to attain even more gradual action in the case of the very large charges required for guns of the heaviest calibres, such as the 110-ton gun, from which shot of about 1800 lbs. weight are propelled by a powder-charge of 960 lbs. Brown powder has, therefore, been modified in composition to suit these conditions; while, on the other hand, a powder intermediate in rapidity of action between black powder and the brown prism powder has been found more suitable than the former for use in guns of moderately large calibre.

The importance which machine-guns and comparatively large, quick-firing guns have assumed in the armament of ships has made it very desirable to provide a powder for them which will produce comparatively little or no smoke, as their efficient employment becomes greatly limited when, after a very few rounds rapidly fired, with black powder, the objects against which it is desired to direct the fire, are more or less completely hidden by the interposed smoke. Hence much attention has of late been directed to the production of smokeless, or nearly smokeless, powders for naval use. At the same time, the views of many military authorities regarding the importance of dispensing with smoke in engagements on land have also created a demand for smokeless powders suitable for field-artillery and for small-arms.

The properties of ammonium-nitrate, of which the products of decomposition by heat are, in addition to water-vapour, entirely gaseous, have rendered it a tempting material to those who have striven to produce a smokeless powder; but its deliquescent character has been a formidable obstacle to its application as a component of a useful explosive agent. By incorporating charcoal and saltpetre in particular proportions with ammonium-nitrate, F. Gaus recently claimed to have produced an explosive material free from the hygroscopic character common to other ammonium-nitrate mixtures, and furnishing only permanently gaseous and volatile, or smokeless, products of explosion. These anticipations were not realized, but they led the talented German powder-maker, Mr. Heidemann, to produce an ammonium-nitrate powder possessing remarkable ballistic properties, and producing comparatively little smoke, which speedily disperses. It yields a very much larger volume of gas and water-vapour than either black or brown powder, and is considerably slower in action than the latter; the charge required to produce equal ballistic results is less, while the chamber-pressure developed is lower, and the pressures along the chase of the gun are higher, than with brown powder. No great tendency is exhibited by it to absorb moisture from an ordinarily dry, or even somewhat moist, atmosphere, but it rapidly absorbs water when the hygroscopic condition of the air approaches saturation, and this greatly restricts its use.

About five years ago reports began to reach us from France of the attainment of remarkable results with a smokeless powder employed with the repeating or magazine rifle then in course of adoption for military service, and of marvellous velocities obtained by the use of this powder, in specially constructed artillery of great length. As in the case of the explosive agent called *Mélinite*, the fabulously-destructive effects of which were much vaunted at about the same time, the secret of the nature of this smokeless powder was well preserved by the French authorities; it is now known, however, that more than one smokeless explosive has succeeded the original, and that the material at present in use with the Lebel repeating rifle belongs to a class of nitro-cellulose or nitro-cotton preparations, of which several have been made the subject of patents in England, and of which varieties are also being used in Germany and other countries.

A comparison between the chemical changes attending the burning or explosion of gunpowder, and of the class of nitro-compounds represented by gun-cotton, at once explains the cause of the production of smoke by the former, and of the

smokelessness of the latter. Whilst the products of explosion of the nitro-compounds consist exclusively of gases and of water-vapour, gunpowder, being composed of a large proportion of saltpetre, or other metallic nitrate, mixed with charred vegetable matter and variable quantities of sulphur, furnishes products of which over 50 per cent. are not gaseous, even at high temperatures, and which are in part deposited as a fused solid—which constitutes the fouling in a firearm—and in part distributed in an extremely fine state of division through the gases and vapours developed by the explosion, thus giving to these the appearance of smoke as they escape into the air.

So far as smokelessness is concerned, no material can surpass *gun-cotton* (or other varieties of nitro-cellulose); but, even if the rate of combustion of the fibrous explosive in a firearm could be controlled with certainty and uniformity, its application as a safe propulsive agent is attended by so many difficulties that the non-success of the numerous early attempts to apply it to that purpose is not surprising. Those attempts, commencing soon after the discovery of gun-cotton, in 1846, and continued many years later in Austria, consisted entirely in varying the density and mechanical condition of employment of the gun-cotton fibre. No difficulty was experienced in thus exercising complete control over the rapidity of burning in the open air; but when the material was strongly confined, as in the bore of a gun, such methods of regulating its explosive force were quite unreliable, as some slight unforeseen variation in its compactness or in the amount and disposition of the air-spaces in the mass, would develop very violent action. Much more promising results were subsequently obtained by me by reducing the fibre to a pulp, as in the ordinary process of making paper, and converting this into highly-compressed, homogeneous masses of the desired form and size. Some favourable results were obtained at Woolwich, in 1867–68, in field-guns, with cartridges built up of compressed gun-cotton variously formed and arranged, with the object of regulating the rapidity of explosion of the charge. But although comparatively small charges often gave high velocities of projection, without any indications of injury to the gun, the uniform fulfilment of the conditions essential to safety proved to be beyond absolute control, even in guns of small calibre; and military authorities not being, in those days, alive to the advantages which might accrue from the employment of an entirely smokeless explosive in artillery, experiments in this direction were not persevered in. At the same time, considerable success attended the production of gun-cotton cartridges for sporting purposes, the rapidity of its explosion being controlled by various methods; very promising results were also attained with the Martini-Henry rifle and a lightly-compressed pulped gun-cotton charge, of pellet-form, the uniform action of which was secured by simple means.

A nearly smokeless sporting-powder had, in the meantime, been produced by Colonel Schultze, of the Prussian Artillery, from finely-divided wood, converted after purification into a mildly explosive form of nitro-cellulose, and impregnated with a small portion of an oxidizing agent. Subsequently this powder was produced in a granular form, and rendered considerably more uniform in character, and less hygroscopic; it then closely resembled the well-known E.C. sporting-powder, which consists of a nitro-cotton reduced to pulp, incorporated with the nitrates of potassium and barium, and converted into grains through the agency of a solvent and a binding material. Both these powders produce very little smoke compared with black powder, but do not compete with the latter in regard to accuracy of shooting, when used in military arms.

In past years both camphor and liquid solvents have been applied to the hardening of the surfaces of granulated or compressed masses of gun-cotton and of this class of its preparations, with a view to render them non-porous. In some smokeless powders of French, German, Belgian, and English manufacture, acetic ether and acetone have been also used, not merely to harden the granules or tablets of the explosive, but also to convert the nitro-cellulose, in the first instance, into a more or less gelatinous condition, so that it can readily be incorporated with other components and rolled, or spread into sheets, or pressed into moulds, or squirted into wires, rods, or tubes, while still in a plastic state. When the solvent has afterwards been removed, the hardened, horn-like, or somewhat plastic product is cut up into tablets, or into strips or pieces of suitable dimensions, for conversation into charges or cartridges.

Another class of smokeless powder, similar in physical characteristics to these nitro-cellulose powders, but containing nitro-glycerine as an important component, has been originated by Mr. Alfred Nobel, the well-known inventor of dynamite, and bears resemblance in its physical characteristics to another of his inventions, called blasting-gelatine, one of the most interesting of known violent explosive agents. When one of the lower products of nitration of cellulose is impregnated with the liquid explosive, nitro-glycerine, it gradually loses its fibrous nature, becoming gelatinized while assimilating the liquid; and the resulting product almost possesses the characters of a compound. This preparation, and certain modifications of it, have acquired high importance as blasting-agents more powerful than dynamite, and are possessed of the valuable property that their prolonged immersion in water does not separate from them any appreciable proportion of nitro-glycerine. The nitro-glycerine powder first produced by Mr. Nobel was almost perfectly smokeless and developed very high energy, accompanied by moderate pressures at the seat of the charge, but it possessed certain practical defects, which led to the development of several modifications of that explosive and various improvements in manufacture. The relative merits of this class of smokeless powder, and of various kinds of nitro-cellulose powder, are now under careful investigation in this and other countries, and several more or less formidable difficulties have been met with in their application, in small-arms especially; these arise in part from the comparatively great heat they develop, which increases the erosive effects of the products of explosion, and in part from the more or less complete absence of solid products. The surfaces of the barrel and of the projectile being left clean, after the firing, are in a condition favourable to their close adhesion while the bullet is propelled along the bore, with the consequent establishment of very greatly increased friction. The latter difficulty has been surmounted by more than one expedient, but always at the cost of absolute smokelessness.

Our knowledge of the results obtained in France and Germany with the use of smokeless powders in the new rifles and in artillery is somewhat limited; our own experiments have demonstrated that satisfactory results are attainable with more than one variety of them, not only in the new repeating-arm of our infantry, but also with our machine-guns, with field-artillery, and with the quick-firing guns of larger calibre which constitute an important feature in the armament of our Navy. The importance of ensuring that the powder shall not be liable to undergo chemical change detrimental to its efficiency or safety, when stored in different localities where it may be subject to considerable variations of temperature (a condition especially essential in connection with our own naval and military service in all parts of the world), necessitates qualities not very easily secured in an explosive agent consisting mainly of the comparatively sensitive nitro-compounds to which the chemist is limited in the production of a smokeless powder. It is possible, therefore, that the extent of use of such a material in our ships, or in our tropical possessions, may have to be limited by the practicability of fulfilling certain special conditions essential to its storage without danger or possible deterioration. If, however, great advantages are likely to attend the employment of a smokeless explosive, at any rate for certain Services, it will be well worth while to adopt such special arrangements as may be required for securing these without incurring special dangers; this may prove to be especially necessary in our ships of war, where temperatures so high as to be prejudicial even to ordinary black powder, sometimes prevail in the magazines, consequent mainly upon the positions assigned to them in the ships, but which may be guarded against by measures not difficult of application.

The Press accounts of the wonderful performances of the first smokeless powder adopted by the French—which, it should be added, were in some respects confirmed by official reports of officers who had witnessed experiments at a considerable distance—engendered a belief that a very great revolution in the conduct of campaigns must result from the introduction of such powders. It was even reported very positively that noiselessness was one of the important attributes of a smokeless powder, and highly-coloured comparisons have, in consequence, been drawn in Service-periodicals, and even by some military authorities, between the battles of the past and those of the future; the terrific din caused by the firing of the many guns and the roar of infantry-fire, in heavy engagements, being supposed to be reduced to noise so slight that distant troops would fail to know in what direction their comrades were engaged, and that sentries and outposts would no longer be able to warn their comrades of the approaching foe by the discharge of their rifles. Military

journals of renown, misled by such legendary accounts, chiefly emanating from France, referred to the absence of noise and smoke in battles as greatly enhancing the demands for skill and courage, and as surrounding a fight with mystery. The absence of recoil when a rifle was fired with smokeless powder was another of the marvels reported to attend the use of these new agents of warfare. It need scarcely be said that a closer acquaintance with them has dispelled the credit given to such of the accounts of their supposed qualities as were mythical, and a belief in which could only be ascribable to a phenomenal combination of credulity with ignorance of the most elementary scientific knowledge.

The extensive use which has been made in Germany of smokeless or nearly smokeless powder in one or two special military displays has, however, afforded interesting indications of the actual change which is likely to be wrought in the conditions under which engagements on land will be fought in the future, provided these new explosives thoroughly establish and maintain their position as safe and reliable propelling agents. Although the powder adopted in Germany is not actually smokeless, the almost transparent film of smoke produced by independent rifle-firing with it is not visible at a distance of about 300 yards; at shorter distances it presents the appearance of a puff from a cigar. The most rapid salvo-firing by a large number of men does not have the effect of obscuring them from distant observers. When machine-guns and field-artillery are fired with the almost absolutely smokeless powder which we are employing, their position is not readily revealed to distant observers by the momentary vivid flash of flame and slight cloud of dust produced.

There now appears little doubt that in future warfare belligerents on both sides will alike be users of these new powders; the screening or obscuring effect of smoke will therefore be practically absent during engagements between contending forces, and while, on the one hand, the very important protection of smoke, and its sometimes equally important assistance in manœuvres, will thus be abolished, both combatants will, on the other hand, secure the advantages of accuracy of shooting and of the use of individual fire, through the medium of cover, with comparative immunity from detection. Such results as these cannot fail to affect, more or less radically, the principles and conditions under which battles have hitherto been fought. With respect to the naval service, it is especially for the quick-firing guns, so important for defensive purposes, that a smokeless powder has been anxiously looked for; by the adoption of such a powder as has during the past year been elaborated for our artillery, should experience establish its reliability under all Service conditions and its power to fulfil all reasonable requirements in regard to stability, these guns will not only be used by our ships under conditions most favourable to their efficiency, but their power will also be very importantly increased.

The ready and safe attainment of very high velocities of projection through the agency of these new varieties of explosive agents, employed in guns of suitable construction, would appear at first sight to promise a very important advance in the power of artillery; the practical difficulties attending the utilization of these results are, however, sufficiently formidable to place, at any rate at present, comparatively narrow limits upon our powers of availing ourselves of the advantages in ballistics which they may present. The strength of the gun-carriages and the character of the arrangements used for absorbing the force of recoil of the gun, need considerable modifications, not easy of application in some instances; greater strength and perfection of manufacture are imperative in the case of the hollow projectiles or shells to be used with charges of a propelling agent by the firing of which in the gun they may be submitted to comparatively very severe concussions; the increased friction to which portions of the explosive contents of the shell are exposed by the more violent setting back of the mass may increase the possibility of their accidental ignition before the shell has been projected from the gun; the increase of concussion to which the fuze in the shell is exposed may give rise to a similar risk consequent upon an increased liability to a failure of the mechanical devices which are applied to prevent the igniting arrangement, designed to come into operation only upon the impact or graze of the projected shells, from being set into action prematurely by the shock of the discharge; lastly, the circumstance that the rate of burning of the time-fuze which determines the efficiency of a projected shrapnel shell is materially altered by an increase in the velocity of flight of the shell, also presents a source of difficulty.

The fallibility of even the most simple forms of fuze, manufactured in very large numbers, although it may be remote, must always engender a feeling of insecurity, when shells are employed containing an explosive agent of the class which, in recent years, it has been sought, by every resource of ingenuity, combined with intimate knowledge of the properties of these explosives, to apply as substitutes for gunpowder in shells, on account of their comparatively great destructive power.

One of the first uses, for purposes of warfare, to which it was attempted to apply gun-cotton, was as a charge for shells. But even when this was highly-compressed, and accurately fitted the shell-chamber, with the intervention only of a soft packing between the surfaces of explosive and of metal, to guard against friction between the two upon the shock of the discharge, no security was attainable against the ignition of the comparatively sensitive explosive by friction established within its mass at the moment when the shell is first set in motion. By the premature explosion of a shell charged with gunpowder, no important injury is inflicted upon the gun, but a similar accidental ignition of a gun-cotton charge must almost inevitably burst the arm. The earlier attempts to apply gun-cotton as a bursting-charge for shells were several times attended by very disastrous accidents of this kind; but the fact, afterwards discovered, that wet compressed gun-cotton, even when containing sufficient water to render it quite uninflammable, can be detonated through the agency of a sufficiently powerful charge of fulminate of mercury, or of a small quantity of dry gun-cotton embedded within it, has led to the perfectly safe application of gun-cotton in shells, provided the fuze, through the agency of which the initiative detonating agent in the shell comes into operation, is secure against any liability to premature ignition when the gun is fired. Many successful experiments have been made with shells thus charged with wet gun-cotton, which is now recognized as a formidable destructive agent applicable in shells with much less risk of casualty than attends the use of many other of the violent explosive bodies which it has become fashionable, in professional parlance, to designate as "high explosives."

Many devices and arrangements, more or less ingenious and complicated, have been schemed, especially in the United States, for applying preparations of the very sensitive liquid, nitroglycerine, such as dynamite and blasting-gelatine, as charges for shells. Some of these consist in subdividing the charge by more or less elaborate methods; in others the shell is also lined with some soft elastic packing-material, and paddings of similar material are applied in the head and the base of the shell-chamber, with the object of reducing the friction and concussion to which the explosive is exposed when the projectile is first set in motion. Such arrangements obviously reduce the space available for the charge in the shell, and the best of them fail to render these explosives as safe to employ as wet gun-cotton. In order to avoid exposing shells loaded with such explosives to the concussion produced when propelling them by a powder-charge, compressed air has been applied as the propelling agent, and guns of special construction and very large dimensions, from which shells containing as much as 500 lbs. of gun-cotton or dynamite are projected through the agency of compressed air, have recently been elaborated in the United States, where great expectations are entertained of the value, for war-purposes, of these so-called pneumatic guns.

A highly ingenious device for utilizing a class of very powerful explosives in shells, without any risk of accident to the gun, was not long since brought forward by Mr. Grüsen, the well-known armour-plate and projectile manufacturer of Magdeburg. It consisted of a thoroughly efficient arrangement for applying the fact, first demonstrated by Dr. Sprengel, that mixtures of nitric acid of high specific gravity with solid or liquid hydrocarbons, or with the nitro-compounds of these, are susceptible of detonation, with development of very high energy. The two agents, of themselves non-explosive—nitric acid and the hydrocarbon, or its nitro-product—are separately confined in the shell; when it is first set in motion by the firing of the gun, the fracture of the receptacle containing the liquid nitric acid is determined by a very sinple device; the two substances are then free to come into contact, and their very rapid mixture is promoted by the rotation of the shell, so that, almost by the time that it is projected from the gun, its contents, at first quite harmless, have become converted into a powerfully explosive mixture, ready to come into operation through the action of the fuze. Although safety appears assured by this system, the comparatively complicated nature of the contrivance, and the loss of space in the

shell thereby entailed, place it at a disadvantage, especially since some other very violent explosive agents have come to be applied with comparative safety in shells.

Between four and five years ago intelligence first reached us of marvellously destructive effects produced by shells charged with an explosive agent which the French Government was elaborating. The reported results surpassed any previously recorded in regard to violently destructive effects and great velocity of projection of the fragments of exploded shells, and it was asserted that the employment of this new material, Mélinite, was unattended by the usual dangers incident to this particular application of violent explosive agents, an assertion scarcely consistent with accounts which soon reached us of several terrible calamities due to the accidental explosion of shells loaded with Mélinite.

Although the secret of the precise nature of Mélinite has been extremely well preserved, it transpired ere long that extensive purchases were made in England, by or for the French authorities, of one of the many coal-tar derivatives which for some years past has been extensively manufactured for tinctorial purposes, but which, although not itself classed among explosive bodies until quite lately, had long before been known to furnish, with some metals, more or less highly explosive combinations, some of which have been applied to the production of preparations suggested as substitutes for gunpowder.

The product of destructive distillation of coal from which, by oxidation, this material is now manufactured, is the important and universally-known antiseptic and disinfectant, carbolic acid, or phenol. Originally designated carbazotic acid, the substance now known as picric acid was first obtained in small quantities as a chemical curiosity by the oxidation of silk, aloes, &c., and of the well-known blue dye indigo, which thus yielded another dye of a brilliant yellow colour. To the many who may regard this interesting phenol-derivative as a material concerning the stability and other properties of which we have little knowledge it will be interesting to learn that it has been known to chemists for more than a century. It was first manufactured in England for tinctorial purposes by the oxidation of a yellow resin (*Xanthorrhœa hastilis*), known as Botany Bay gum. Its production from carbolic acid was developed in Manchester in 1862, and its application as a dye gradually extended, until, in 1886, nearly 100 tons were produced in England and Wales.

Although picric acid compounds were long since experimented with as explosive agents, it was not until a very serious accident occurred, in 1887, at some works near Manchester where the dye had been for some time manufactured, that public attention was directed in England to the powerfully explosive nature of this substance itself. The French authorities appear, however, to have been at that time already engaged upon its application as an explosive for shells. It is now produced in very large quantities at several works in Great Britain, and it has been extensively exported during the last four years, evidently for other than the usual commercial purposes. Large supplies of phenol, or carbolic acid, have, at the same time, been purchased in England for France, and lately for Germany, doubtless for the manufacture of picric acid, very extensive works having been established for its production in both those countries. It has been made the subject of experiment by our military authorities, and its position has been well established as a thoroughly stable explosive agent, easily manufactured, comparatively safe to deal with, and very destructive when the conditions essential for its detonation are fulfilled.

The precise nature of Mélinite appears to be still only known to the French authorities: it is asserted to be a mixture of picric acid with some material imparting to it greater power; but accounts of accidents which have occurred even quite recently in the handling of shells charged with that material appear to show that, in point of safety or stability, it is decidedly inferior to simple picric acid. Reliable as the latter is in this respect, its employment is, however, not unattended with the difficulties and risks which have to be encountered in the use, in shells, of other especially violent explosives. Future experience in actual warfare can alone determine decisively the relative value of violent explosive agents, like picric acid or wet gun-cotton, and of the comparatively slow explosive, gunpowder, for use in shells; it is certain, however, that the latter still presents distinct advantages in some directions, and that there is no present prospect of its being more than partially superseded as an explosive for shells.

With regard to submarine mines and locomotive torpedoes, such as those marvels of ingenuity and constructive skill, the Whitehead and Brennan torpedoes, the important progress recently made in the practical development of explosive agents has not resulted in the provision of a material which equals wet compressed gun-cotton in combining with great destructive power the all-important essential of safety to those who have to deal with these formidable weapons, and to man the small vessels which have to perform the very hazardous service of attacking ships of war at short distances by means of locomotive torpedoes.

Although the subject of the development of explosive force for purposes of war has of late received from workers in applied science, from seekers of patentable inventions, and even from the public generally, a somewhat predominating share of attention, considering that we congratulate ourselves upon the enjoyment of a period of profound peace, yet the production of new explosive agents for mining and quarrying purposes, which present or lay claim to points of superiority over the well-established blasting-agents, has been by no means at a standstill. For many years the main object sought to be achieved in this direction was to surpass, in power or adaptability to particular classes of work, the well-known preparations of nitro-glycerine and gun-cotton, which, during the past twenty years, have been formidable competitors and, in many directions, absolutely successful rivals, of black powder. It is both interesting and satisfactory to note, however, that this object has of late, and especially since the publication of the results of labours of English and foreign Commissions on the causes of mine-accidents, been prominently associated with endeavours to solve the important problems of combining, in an explosive agent, efficiency in point of power with comparative non-sensitiveness to explosion by friction or percussion, and of securing its effective operation with little or no accompaniment of projected flame. Safety-dynamites, flameless explosives, water-cartridges, and other classes of materials and devices connected with the getting of coal, the quarrying of rock, or the blasting of minerals, have claimed the attention of those who guide the miner's work; in some of these directions the practical results obtained have been beyond question important, and, indeed, conclusive as regards the great diminution of risks to which men need be exposed in those coal-mines where the ordinary use of explosives, although not altogether inadmissible, may at times be attended with danger. It is to be feared that those results are still far from receiving the amount of application which might reasonably be hoped for; but, at any rate, there are, among the extensive mining districts where the employment of explosives in connection with the getting of coal cannot be dispensed with, several of importance where the use of gunpowder has almost entirely given place to the adoption of blasting-agents or methods of blasting, the employment of which is either not, or only very exceptionally, attended by the projection of flame or incandescent matter into the air where the shot is fired.

The mining public is especially indebted to German workers for much of the success which has been obtained in this direction, and also to the eminent French authorities, Mallard and Le Chatelier, for their thorough theoretical and practical investigations bearing upon the prevention of accidental ignition of fire-damp during blasting operations. Having arrived at the conclusion that fire-damp- and air-mixtures are not ignited by the firing of explosive preparations which develop by their detonation temperatures lower than 2220° C., they found that ammonium-nitrate, although in itself susceptible of detonation, does not develop a higher temperature than 1130° C., while the temperature of detonation of nitro-glycerine and gun-cotton are, respectively, 3170° and 2636°. The admixture of that salt with nitro-glycerine or gun-cotton in sufficient proportion to reduce the temperature of detonation to within safe limits allows, therefore, of the employment of those explosive agents in the presence of fire-damp mixtures without risk of accident, and this fact has led to the effective use of such mixtures as safe blasting-agents in coal.

Those who have been content to labour long and arduously with the objects steadily in view of advancing our knowledge of the causes of mine-accidents and of developing resources and measures for removing or combating those causes, can cherish the conviction that recent legislation in connection with coal-mines, based upon the results of those labours, has been already productive of decided benefits to the miner, even although it has fallen short of what might reasonably have been

hoped for as an outcome of the very definite results and conclusions arrived at by the late Royal Commission on Accidents in Mines (in the recent much-lamented death of whose universally respected chairman, my late esteemed friend and colleague, Sir Warington Smyth, the scientific world has sustained the loss of an ardent worker, and the miner, of an invaluable friend).

The fearful dangers arising from the accumulation of inflammable dust in coal-mines, and the equality of mine-dust with fire-damp in its direful power of propagating explosions, which may sometimes even be, in the first instance, established chiefly or entirely through its agency, have now been long recognized as beyond dispute; and it is satisfactory to know that permission to fire shots in mine-workings which are dry and dusty has, by recent legislation, been made conditional upon the previous laying of the dust by effective watering. In some mining districts, moreover, the purely voluntary practice has been extensively adopted by mine-owners of periodically watering the main roads in dry and dusty mines, or of frequently discharging water-spray into the air in such roads, which must tend greatly to reduce the possible magnitude of the disastrous results of a fire-damp or dust explosion in any part of the mine-workings.

The encouragement given to the application of the combined resources of ingenuity, mechanical skill, and knowledge of scientific principles, through the elaborate, but thoroughly practical comparative trials to which almost every variety of safety-lamp has, during the last few years, been submitted by competent and conscientious experimenters, has resulted in the provision of lamps to the hand of the miner which combine the essential qualities of safety, under the most exceptionally severe conditions, with good illuminating power, simplicity of construction, lightness, and moderate cost. Very important progress has also been made, since the first appointment of the late Accidents in Mines Commission, towards the provision of thoroughly serviceable and safe portable electric lamps for use in mines. Of those which have already been in the hands of the miners, several have fairly fulfilled his requirements as regards size, weight, and illuminating power of sufficient duration; but much still remains to be accomplished with respect to durability, simplicity, thorough portability, and cost, before the self-contained electric lamp can be expected to compete successfully with the greatly improved miners' lamps which are now in use, or available.

The recent legislation in connection with mines is certainly deficient in any sufficiently decisive measure for excluding from mine-workings certain forms of lamps which, while fairly safe in the old days of sluggish ventilation, are unsafe in the rapid air-currents now frequently met with in mines; it is, however, very satisfactory to know that the strong representations on this subject made by the late Commission, combined with the force of example and with the conclusive demonstration of the superiority of other lamps, by exhaustive experiments, have led within the last two years to the very general abandonment of the unprotected Davy, Clanny, and Stephenson lamps in favour, either of simple, safe modifications of these, or of other safe and efficient lamps, and that one possible element of danger to the miner has thus been eliminated, at any rate in many districts. In one important respect recent improved legislation has failed to effect a most desirable change—namely, in the substitution of safety-lamps for naked lights in workings where small local accumulations of fire-damp are discovered from time to time. There appears little doubt that one of the three fearful explosions which have occurred within the last twelve months—the explosion at Llanerch Colliery, near Pontypool—was caused by the continued employment of naked lights in a mine where inspection constantly revealed the presence of fire-damp. This, and two other terrible disasters, at Mossfield Colliery, in Staffordshire, at Morfa Colliery, near Swansea, which have occurred since the last meeting of the Association, may have seemed to weaken the belief that the operation of the recent Mines Regulation Act, which was based upon some of the results of seven years' arduous labour of the late Mines Commission, must have resulted in very substantial improvement in the management of mines and in the conduct of work by the men. Happily, however, there is a consensus of opinion among those most competent to judge—*i.e.* the Government Mine Inspectors—that very decided benefits have already accrued from the operation of the new Act. Although far from embodying all that the experienced mine-owners, miners, and scientific workers upon that Commission, as well as practical authorities in Parliament, concurred in regarding as reasonably adaptable, from the results of observation and experiment, to the furtherance of the safer working of mines, this Act does include measures, precautionary and preventive, of undeniable utility, well-calculated to lessen the dangers which surround the miner, and to add to his personal comfort underground. We may hope, moreover, that the operation of the Act is paving the way to more comprehensive legislation in the near future; for it can scarcely be doubted, by the light of recent sad experience, that there are directions in which both masters and men still hesitate to adopt, of their own free will, measures or regulations, methods of working or appliances and precautions, which are calculated to be important additional safeguards against mine-accidents, and which are either left untouched, or only hesitatingly and imperfectly dealt with in the recent enactments.

My labours upon the late Mines Commission represent only one of several subjects in connection with which it has been my good fortune to have opportunities of rendering some slight public service in directions contrasting with one of the main functions of my career, by endeavouring to apply the results of scientific research to a diminution of the risks to which particular classes of the community, or the public at large, are exposed—of being sufferers by explosions, the results of accidents or other causes.

During the pursuit of bread-winning vocations, and even in ordinary domestic life, the conditions, as well as the materials, requisite for determining more or less disastrous explosions are often ready to hand, and their activity may be evoked at any moment through individual heedlessness or through pure accident. Steam, or gases confined under pressure, volatile inflammable liquids, combustible gases, or finely-divided inflammable solids, are now all well recognized as capable of assuming the character of formidable explosive agents; but with respect to the three last-named, it is only of late that material progress has been made towards a popular comprehension and appreciation of the conditions conducive to danger, and of those by the fulfilment of which danger may be avoided. Thus, the causes of explosions in coal-laden ships, together with the occurrence of spontaneous ignition in coal-cargoes, another fruitful source of disaster, were made the subject of careful inquiry some years ago by a Royal Commission, upon which I had the pleasure of working with the late Dr. Percy, whose invaluable labours for the advancement of metallurgic science will always be gratefully remembered. The light thrown by that inquiry upon the causes of those disasters, and upon the conditions to be fulfilled for guarding against the accumulations of fire-damp, gradually escaping from occlusion in coal, and of heat, developed by chemical changes occurring in coal-cargoes, has unquestionably led to an important reduction of the risks to which coal-laden ships are exposed. Subsequent official inquiries and experimental investigations, in which I took part with the late Sir Warington Smyth and some eminent naval officers, consequent upon the loss of H.M.S. *Doterel* through the accidental ignition of an explosive mixture of petroleum spirit-vapour and air (and other calamities in war-ships originating with the gradual emission of fire-damp from coal), have resulted in the adoption of efficient arrangements for ventilating all spaces occupied by, and contiguous to, the large supplies of fuel which these vessels have to carry.

The thorough investigation, by Rankine and others, of the causes of explosions in flour-mills, which in years past were so frequent and disastrous, has secured the adoption of efficient measures for diminishing the production, and the dissemination through channels and other spaces in the mills, of explosive mixtures of flour-dust and air, and for guarding against their accidental ignition. The numerous terrible accidents caused by the formation and accidental ignition of explosive mixtures of inflammable vapour and air in ships carrying cargoes of petroleum stored in barrels or in tanks, have, by the investigations to which they have given rise, led to the indication of effective precautionary measures for guarding against their recurrence. Again, the many distressing accidents, frequently fatal, which have attended the domestic use of those valuable illuminants, petroleum and mineral oils of kindred character, have been made the subject of exhaustive investigations, which have demonstrated that these disasters may readily be prevented by the employment of lamps of proper construction, and by the observance of very simple precautions by the users of them; and a

recent official inquiry which I have conducted with Mr. Boverton Redwood has furnished most gratifying proof that very substantial progress has been made within the last few years by lamp-manufacturers in the voluntary adoption of such principles of construction as we had experimentally demonstrated to be essential for securing the safe use of mineral oils in lamps for lighting and heating purposes, the employment of which has, within a brief period, received enormous extension in this and other countries.

The creation and rapid development of the petroleum industry has, indeed, furnished one of the most remarkable illustrations which can be cited of industrial progress during the period which has elapsed since the British Association last met in Leeds. One year after that meeting, viz. on August 28, 1859, the first well, drilled in the United States with the object of obtaining petroleum, was successfully completed, and the rate of increase in production in the Pennsylvania oil-fields during the succeeding years is shown by the following figures:—

In 1859, 5000 barrels (of forty-two American gallons) were produced In the following year the production increased to 500,000 barrels; while in the next year (1861) it exceeded 2,000,000 barrels, at which figure it remained, with slight fluctuations, until 1865. The supply then continued to increase gradually, until, in 1870, it reached nearly 6,000,000 barrels; while in 1874 it amounted to nearly 11,000,000 barrels. In 1880 it amounted to over 26,000,000 barrels, and in 1882 it reached 31,000,000. Since then the supply furnished by the United States has fallen somewhat, and last year it amounted to 21,500,000 barrels. The production of crude petroleum in the Pennsylvanian fields, large as it has been, has not, however, kept pace with the consumption, for we find that the accumulated stocks, which on December 31, 1888, amounted to over 18,000,000 barrels, had become reduced to about 11,000,000 barrels at the close of last year. At this rate the surplus stock above ground will have vanished by the end of the current year. In addition to the petroleum raised in Pennsylvania, there is now a very large production in the State of Ohio; but this has not as yet been employed as a source of lamp-oil; it is, however, transported by pipe line in great quantities to Chicago, for use as liquid fuel in industrial operations.

A few years after the development of the United States petroleum-industry, the production of crude petroleum in Russia also began to extend very rapidly. For more than 2500 years, Baku, on the borders of the Caspian Sea, has been celebrated for its naphtha springs, and for the perpetual flames of the Fire Worshippers, fed by the marvellous subterranean supplies of natural gas. To a limited extent neighbouring nations appear to have availed themselves of the vast supplies of mineral oil at Baku during the past thousand years. By the thirteenth century the export of the crude oil had already become somewhat extensive, but the production of petroleum from it by distillation is of comparatively recent date. In 1863 the supplies of petroleum from the Baku district amounted to 5018 tons; they increased to somewhat more than double during the succeeding five years. In 1869 and following three years the production reached about 27,000 tons annually, and in 1873 it was about 64,000 tons; three years later, 153,000 tons were produced, and in the following five years there was a steady annual increase, until, in 1882, the production amounted to 677,269 tons; in 1884 it considerably exceeded 1,000,000 tons, and last year it had reached the figure of about 3,300,000 tons. The consumption of crude petroleum as fuel for locomotive purposes has, moreover, now assumed very large proportions in Russia, and many millions of gallons are annually consumed in working the vast system of railways on both sides of the Caspian Sea.

The imported refined petroleum used in this country in lamps for lighting, heating, and cooking, was exclusively American until within the last few years, but a very large proportion of present supplies comes from Russia. The imports of kerosene into London and the chief ports of the United Kingdom during 1889 amounted to 1,116,205 barrels of United States oil, and 771,227 barrels of Russian oil. During the same period the outturn of mineral oil for use in lamps by the Scottish shale oil companies probably amounted to about 500,000 barrels.

Another important feature connected with the development of the petroleum industry is the great extent to which the less volatile products of its distillation have replaced vegetable and animal oils and fats for lubricating purposes in this and other countries. The value of petroleum as a liquid fuel and as a source of gas for illuminating purposes has, moreover, been long since recognized, and it is probable that one outcome of the attention which is now being given to the hitherto unworked deposits of petroleum in the East and West Indies, South America, and elsewhere, will be a very large increase in its application to these purposes. In the East Indies there are vast tracts of oil-fields in Burmah, Baluchistan, Assam, and the Punjab. The native Rangoon oil industry is one of great antiquity, although the oil was only used in the crude condition until about thirty-five years ago, at which time Dr. Hugo Müller, with the late Warren De la Rue, whose many-sided labours and generous benefactions have so importantly contributed to the advancement of science, made valuable researches on the products furnished by crude oil imported from Rangoon. The resources of the oil-fields of Upper Burmah, especially of the district of Yenangyoung (or *creek of stinking water*), have since then been developed by British enterprise, and have attained to considerable importance since our annexation of Upper Burmah.

The great extension of the petroleum trade is gradually leading to very important improvements in the system of transport of the material over water and on land. Until recently this has been carried out entirely in barrels and tin cases; the consequent great loss from leakage and evaporation, accompanied by risk of accident, is now becoming much reduced by the rapidly-increasing employment of tank-steamers, which transport the oil in bulk. Tank railway-waggons have for some time past been in use in Russia, and there is a prospect of these and of tank-barges being adopted here for the distribution of the oil; while in London, the practice is already spreading gradually of distributing supplies to tradesmen from tank-road-waggons. Some considerable doubt as to whether the risk of accident has not rather been altered in character than actually reduced by the new system of transport, has not unnaturally been engendered in the public mind by the occurrence within a comparatively short period of several serious disasters during the discharge of cargoes from tank-vessels. The memorable explosion which took place, in October 1888, on board the *Ville de Calais*, in Calais Harbour, with widespread destructive effects, was followed by a similarly serious explosion in the *Fergusons*, at Rouen, last December, and, more recently, by a fire of somewhat destructive character at Sunderland, resulting from the discharge into the river of petrolem-residues from a ship's tanks. In all these cases the petroleum was of a nature to allow inflammable vapour to escape readily from the liquid, so that an explosive mixture could be rapidly formed by its copious diffusion through the air. No similar casualty has been brought to notice as having happened to tank-ships carrying petroleum oil of which the volatility is in accordance with our legal requirements, and this points to the prudence of restricting the application of the tank system to the transport and distribution of such petroleum as complies with well-established conditions of safety.

Another most remarkable feature connected with the development of the petroleum industry is presented by the utilization, within the last few years, of the vast supplies of natural inflammable gas furnished by the oil-fields.

In America this remarkable gas-supply was for a long time only used locally, but, before the close of 1885 its conveyance to a distance by pipes, for illuminating and heating purposes, had assumed large proportions; one of the companies in Pittsburgh having alone laid 335 miles of pipes of various sizes, through which gas was supplied equivalent in heating value to 3,650,000 tons of coal per annum. Since then the consumption in and around Pittsburgh has probably been at least tripled. At the close of 1886 six different companies were conveying natural gas by pipes to Pittsburgh from 107 wells; 500 miles of pipe, ranging in diameter from 30 inches to 3 inches, were used by these companies, 232 miles of which were laid within Pittsburgh itself. The Philadelphia Company, the most important of these associations, then owned the gas supply from 54,000 acres of land situated on all the anticlinals around Pittsburgh, but drew its supplies only from Tarentum and the Murraysville field. It supplied, in 1886, 470 factories and about 5000 dwellings within the city, besides many factories and dwellings in Alleghany, and in numerous neighbouring villages. The average gas-pressure at the wells, when the escape is shut off, is about 500 lbs. per square inch, and in the case of new wells this pressure is very greatly exceeded. In order to minimize the danger from leakage the gas-pressure in the city is reduced to a maximum of 13 lbs., and is regulated by valves at a number of stations under the control of a central station. The usual pressure in the larger

lines is from 6 to 8 lbs., while in the low-pressure lines it does not exceed 4 to 5 ounces.

The effect of the change from coal-gas to natural gas upon the atmosphere over Pittsburgh has been most marked: formerly the sky was constantly obscured by a canopy of dense smoke; now the atmosphere is clear, and even white paint may with impunity be employed for the house fronts.

The very rapid development of the employment of natural gas is not confined to the neighbourhood of Pittsburgh; it is used for heating purposes in the cities of Buffalo, Erie, Jamestown, Warren, Olean, Bradford, Oil City, Titusville, Meadville, Youngstown, and perhaps twenty more towns and villages in Pennsylvania and North-western New York. In North-western Ohio, the cities of Toledo and Sandusky, the towns of Findlay, Lima, Tiffin, Fostoria, and others in that section are also supplied with natural gas; a pipe line has moreover been recently laid to Detroit, Mich., and it is estimated that in these localities 36,131,669,000 cubic feet of the gas were consumed during last year, displacing 1,802,500 tons of coal. To the south-west of Pittsburgh there are many smaller places which consume natural gas; it also occurs in considerable quantity, and is being utilized, in Indiana (whence an account has recently reached us of a terrific subterranean explosion of the gas); and it is at the present time contemplated to carry a natural gas-supply to Chicago.

The utilization of the natural gas of the Russian oil-fields, although of very ancient date, has hitherto not been extensive, neither does the magnitude of the supply appear to bear comparison with that of the Pennsylvanian district.

A form of gaseous fuel which has long been known to technical chemists and metallurgists, but which has of late attracted considerable attention, especially in connection with the recent interesting work relating to its applications pursued by Mr. Samson Fox, of Leeds, has become, within the last four years, a competitor, in the United States, both of the natural gas of Pennsylvania and of coal-gas. Since Felix Fontana first produced so-called water-gas in 1780, by passing vapour of water over highly-heated fuel, many methods, differing chiefly in small details, have been proposed for carrying out the operation, with a view to the ready and cheap production of the resulting mixture of hydrogen and carbonic oxide, and numerous technical applications of water-gas have been suggested from time to time, with no very important results, excepting as regards its use for lighting-purposes. Being of itself non-luminous, its utilization in this direction is accomplished, either by mixing it with a highly luminous gas, or by causing a hydrocarbon vapour to be diffused through it; or the non-luminous flame, produced by burning it in the air, is made to raise to incandescence some suitably prepared solid substance, such as magnesia, lime, a zirconium salt, or platinum, whereby bright light is emitted. The objection to its employment as an illuminant for use in buildings, to which great weight is attached by us, and rightly, as sad experience has shown—viz. that, as it consists, to the extent of about one-half its volume, of the highly poisonous gas carbonic oxide, the atmosphere in a confined space may be rendered irrespirable by a small accidental contamination with water-gas, by leakage or otherwise, not detectable by any odour—appears to constitute no great impediment to its employment in the United States, as it is now manufactured for illuminating and heating purposes by a large proportion of their gas-works, being in some places employed in admixture with a highly luminous coal-gas, in others rendered luminous by the alternative methods mentioned. It is stated that about three-fourths of the illuminating gas now supplied to the cities of New York, Brooklyn, Philadelphia, Jersey, St. Paul, and Minneapolis, is carburetted water-gas; in Chicago the entire supply now consists of this gas, and Boston will also soon be supplied exclusively with it. The use of water-gas for metallurgic work does not appear to be contemplated in the United States, but it is especially to such applications of the gas that much attention has been devoted here in Leeds; and although some eminent experts are sceptical regarding the attainment of advantages, especially from an economical point of view, by the employment of this form of gaseous fuel, especially after practical experience in the same direction acquired in Germany, the technical world must feel grateful to Mr. Fox for his work in this direction, affording, as it does, an interesting illustration of the qualities of perseverance and energy which, when combined with sound knowledge, often achieve success in directions that have long appeared most unpromising—qualities which have been characteristic of many pioneers in industrial progress in this country.

Leeds has been especially fortunate in the possession of such pioneers, who, when competition brought about great changes in the particular trade through which, for many generations, this city chiefly enjoyed prosperity and high renown, developed its power and resources in new directions, from which success soon flowed in continually increasing measure. The rapid rise of Leeds to its present high position in industrial prosperity and national importance most probably dates from the period when its chief staple industry began to experience serious rivalry, in its own peculiar achievements, on the part of other districts of the kingdom and of other countries. From early days a flourishing centre of one of the provinces of Great Britain most richly endowed with some of Nature's best treasures, Leeds could scarcely have failed, through the energy, acute intelligence, and powerful self-reliance especially characteristic of the men of Yorkshire, to rapidly acquire fresh renown in connection with industries which either were new to the town and district, or had been pursued in comparatively modest fashion, and which have combined to place the Leeds of to-day upon a higher pinnacle of commercial prosperity, power, and influence than her patriotic citizens of old could ever have dreamt of.

An examination into the present educational resources of Leeds places beyond any doubt the fact that her present prosperity in commerce and industries is in no small degree ascribable to the paramount importance long since attached here to the liberal provision of facilities for the diffusion of knowledge among the artisan- and industrial-classes, and especially for the acquisition of a sound acquaintance with the principles of the sciences and their applications to technical purposes, with particular reference to the prominent local industries, by all grades of those who pursue or intend to pursue them. There is, probably, no town in the kingdom more amply provided with efficient elementary and advanced schools for both sexes, while the special requirements of the artisan are efficiently met by the prosperous School of Science and Technology. The resources of the Yorkshire College provide, in addition, a combination of thorough scientific education with really practical training in the more important local industries; indeed, during the sixteen years of its continually-progressive work, this institution has acquired so widespread a reputation that students come from abroad to reap the advantages afforded by the unrivalled textile and dyeing departments of the Leeds College. The keen competition now existing between these departments and the corresponding branches of the much younger but most vigorous sister College at Bradford, can only conduce to the further development of both, and to their thorough maintenance up to the requirements of the day.

The very important pecuniary aid afforded to these establishments, and to a number of other technical schools in Yorkshire, by one of the most important of the ancient Companies of the City of London, the Clothworkers, affords an interesting illustration of the good work in the cause of education performed by those Guilds, and, especially of late years, by means of their flourishing Institute for the advancement of technical education, which, through its two great instructional establishments in London, and through the operation of its system of examinations throughout the country, extending now even to the colonies, has afforded very important aid towards eradicating the one great blot upon our national educational organization. To have been first in the field in practically developing a far-reaching scheme for the advancement of technical education in this country must continue to be a source of pride to the City of London and its ancient Guilds in time to come, when the operation of efficient legislation, supported and extended by patriotic munificence and by the hearty co-operation of associations of earnest and competent workers in the cause, shall have placed the machinery and resources for the technical instruction of the people upon a footing commensurate with our position among nations.

The remarkable address delivered by Owen here in 1858, wherein the condition, at that time, of those branches of natural science which he had made particularly his own was most comprehensively reviewed, included some especially interesting observations on the importance to the cultivation and progress of the natural sciences, and to the advancement of education of the masses in this country, of providing adequate space and resources for the proper development of our national Museum of Natural History; and it cannot but be a source of great satisfaction and pride to him to have lived to witness the thoroughly successful realization of the objects of his own

indefatigable strivings and powerful advocacy in that direction. Comprehensive as were the views adopted by Owen regarding the scope and possible extension of that Museum, it may, however, be doubted whether they ever embraced so extensive a field as was presented for our contemplation by his successor last year, when he told us that a natural history museum should, in its widest and truest sense, represent, so far as they can be illustrated by museum-specimens, all the sciences which deal with natural phenomena, and that the difficulties of fitly illustrating them have probably alone excluded such subjects as astronomy, physics, chemistry, and physiology, from occupying departments in our national Museum of Natural History.

The application, in its broadest signification, of the title, Natural History Museum, may doubtless be considered to include, not only illustrations and examples of the marvellous works of the Creator and of the results of man's labours in tracing their intimate history and their relations to each other, but also illustrations of the means employed, and of the results attained, by man in his strivings to fathom and unravel the laws by which the domains of Nature are governed. But the reason why representative collections, illustrative of the physical sciences, do not form part of our national Natural History Museum, has, I venture to think, scarcely been correctly ascribable to any difficulty of organizing fit illustrations of methods of investigation, of the attendant appliances, and of the results obtained by experimental research; it appears, rather, to exist in the fact that physical science has hitherto had no share in such a combination of circumstances as has been favourable to the good fortunes and advancement of the natural sciences, and as is analogous to those which, from time to time, give rise to the provision of increased accommodation for our national art treasures. Our present national Science Collection, which has, indeed, had a struggle for existence, does not owe the development it has hitherto experienced to any such moral pressure as has been several times exercised in the case of our art collections, by the munificence of individuals, with the result of securing substantial aid from national resources; its gradual increase in importance has been due to the untiring perseverance of men of science, and of a few prominent influential and public-spirited authorities, in keeping before the public the lessons taught by careful inquiries, such as those intrusted to the Royal Commission on Scientific Instruction, into the opportunities afforded for the cultivation of science and the development of its applications, in other countries, as compared with those provided here.

The success of the efforts made in 1875 by a committee thoroughly representative of every branch of experimental science, to bring together in London an international loan collection of scientific apparatus, and the widespread interest excited by that collection, led the President of the Royal Society, in union with many distinguished representatives of science, to lay before our Department of Education a proposal to establish a national museum of pure and applied science, including the Museum of Inventions, which had already existed since 1860 as a nucleus of a science museum, the establishment whereof had formed part of the original scheme of the Science and Art Department. The Loan Collection of 1876 did, in fact, and in consequence of the urgent representations then made, first put into practical shape the long-cherished desire of men of science to see an institution arise in England similar to the Conservatoire des Arts et Métiers of France, and it became the starting-point of the national collection, representative of the several branches of experimental science, which has been undergoing slow but steady development since that time, patiently awaiting the provision of a suitable home for its contents. This collection, which illustrates not only the means whereby the triumphs of research in experimental science have been and are achieved, but also the methods by which these departments of science are taught, yields, small as it is, to none of our national museum-treasures in interest and importance.

In yet another way did that Loan Collection become illustrious: one of the most interesting features connected with it was the organization of a series of important conferences and explanatory lectures, serving to illustrate, and also greatly to enhance, its value, and affording most invaluable demonstration of the way in which such collections must exercise direct influence upon the advancement of science and upon the diffusion of scientific knowledge. These lectures and conferences demonstrated the wisdom of the suggestion made by the illustrious representative of associated science in Leeds eighteen years previously, that public access to museums should be combined with the delivery of lectures emphasizing and amplifying the information afforded by their contents. The example there set of thoroughly utilizing for instructional purposes, and for the advancement of science, a collection illustrative of the physical sciences, has since been followed by the Science and Art Department; illustrative lectures connected with the existing nucleus of a national science collection, have been delivered from time to time, and the objects in the collection are constantly utilized in the courses of instruction of the adjoining Normal School of Science.

Although the national importance of thoroughly representative and continously-maintained science collections has long been manifest, not only to all workers in science, but also to all who have cared to inquire, even superficially, into the influence of the cultivation of science upon the industrial and commercial prosperity of the country, the labours of a Royal Commission, and of successive Committees, in demonstrating the necessity for the provision of adequate accommodation for such collections, and for their support upon the basis of that afforded to the natural history collections, have been very long in bearing fruit. However, lovers of science, and those who have the prosperity of the country near at heart, have at length cause for rejoicing at the acquisition by the nation of a site in all respects suitable and adequate for the accommodation of the science collections, which, as soon as appropriate buildings are provided for their reception, will not fail, in comprehensiveness and completeness, to become worthy of a country which has been the birthplace of many of the most important discoveries in science, and of a people who have led the van among all nations in making the achievements of science subservient to the advancement of industries and commerce.
